gaps in the common duct with a rubber tube. The omentum was wrapped and sutured about the tube. He concluded that the straight rubber tube should not pass into the lumen of the duodenum if required to stay in place for a long while. In later observations he concluded that this type of operation should be suitable for some cases of carcinoma extending up the duct the drawback being that the opening was not valvular. The Mayo technique of direct anastomosis, with a semilunar opening into the duodenum was popular because of the valvular effect obtained by the semilunar duodenal opening. Walton found the duct was often so short that the direct implantation into the duodenum was difficult. Lahey has reported best results from repair around a T tube. He also used a straight tube for repair and removed it after 7 years of normal biliary function and replaced it with another which is still functioning satisfactorily. Fascial repair is described by Davis and Lewis and others.

We have had 10 cases in which umbrella catheters have been used to repair the common duct. In 7 cases the tube was used to bridge malignant lesions extending from the junction of the cystic duct downward to and including the ampulla of Vater and the pan-

Fig. 5 Shows the umbrella catheter in place in Case 10.

creas. Anastomosis between the common duct and the duodenum was made quickly with an umbrella catheter. Jaundice and intense itching disappeared and the bile was retained in the intestinal tract. Six of these patients have

Fig. 6 Shows method of inserting head of umbrella catheter into side of duct.

Fig. 7 Roentgenogram of Case 6 taken 3 years after operation

died from metastatic carcinoma but were relieved of symptoms of obstructive jaundice.

The seventh patient is still alive. She had cholelithiasis and early adenocarcinoma at the junction of the cystic and common duct. On May 5, 1945 we removed her gall bladder and inserted a T tube in the common duct above the tumor. Her general condition at the time was not good and icteric index was 54. On January 14, 1946 she pulled out the T tube and immediately developed symptoms of biliary obstruction with an icteric index of 60 and intense itching. A second operation was performed on January 24, 1946. At this time we removed the common duct from the junction of the hepatics well down to the ampulla. The distal end was doubly ligated. The common duct stub was connected to the duodenum with an umbrella catheter. Biopsy of an enlarged regional lymph node showed no malignant condition. The liver showed no gross evidence of metastasis. On April 24, 1946 twelve weeks following operation this patient's icteric index was 7. Her weight and general condition were normal. It was evident, on roentgenologic examination on April

30, 1946 that the umbrella catheter was in the same place as it was at the time of operation (Fig. 3).

In Cases 8, 9 and 10 there was no evidence of malignancy; the obstruction was due to benign causes, and the patients are enjoying a normal existence after similar operations have been carried out.

In Case 10 the patient was first operated upon elsewhere on November 1, 1942. The gall bladder containing stones was removed. Following the operation there was bile drainage until December 1, 1942, when it ceased and was immediately followed by symptoms of obstructive jaundice. In January 1943 in a second hospital a surgical attempt to relieve the obstructive jaundice failed. In June, 1943 in the same hospital, a second attempt to relieve the obstructive jaundice failed. In March 1945 (3 years and 5 months following the first operation) in a third hospital a metallic tube was inserted in the common duct. There was a marked improvement in jaundice and general condition for 60 days. In June, 1945 the patient again became jaundiced and x-ray examination showed absence of the metallic tube.

In May 1946 4 years and 7 months following the first operation the patient entered the hospital. There were marked signs of obstructive jaundice and pain that required morphine, $\frac{1}{4}$ grain every 3 hours. May 13, 1946 after the usual preparation of a severely jaundiced patient with proved marked liver damage, an umbrella catheter (Fig. 5) was inserted between the bulged proximal end of the common duct and the duodenum. Before closing the wound cholangiographic examination (Fig. 4) shows the hepatic radicles open and the common duct completely obstructed. This patient was dismissed from the hospital on the eighteenth postoperative day. The icteric index was normal and with the aid of a psychiatrist, as morphine had been given for 2 days. We are quite confident that the use of the umbrella catheter in this case will restore this individual to as nearly a normal existence as is possible after $4\frac{1}{2}$ years of nearly complete obstructive jaundice.

We wonder how the complications following this type of repair will compare with those

following other types of procedure such as (1) transplantation of an internal biliary fistula, (2) end to-end anastomosis of the common duct, (3) hepaticoduodenostomy, (4) choledochoduodenostomy, and (5) repair of the duct over a T tube

SUMMARY

A simplified procedure has been presented for repair of the common duct by means of an umbrella catheter to form an internal biliary fistula.

1 An umbrella catheter is placed between the proximal and distal stubs of the common duct. The catheter is not removed unless obstruction occurs.

2 Incrustation of the tube is probably diminished by the direct and unobstructed flow of bile into the intestine due to the absence of the ampulla of Vater

3 In the 10 cases in which this operation was performed, no umbrella catheters have been displaced, there has been no bile drainage and no duodenal fistulas have developed

4 In 1 case (Fig 2) the internal biliary fistula is functioning 2 years after loss of the tube in the intestine

5 We believe that cicatricial contraction is less likely to occur the longer the tube remains *in situ* before it is removed

6 Cholangitis is not a complicating factor in these cases.

7 It is not known what percentage of internal biliary fistulas will close or how long they will stay open

The method which we have described might be called nonsurgical according to well known operative procedures but our experience continues to be encouraging. We believe this to be a most satisfactory method of repair of the common duct.

UNILATERAL EXOPHTHALMOS AN EARLY SIGN IN THYROTOXICOSIS

WENDELL H. KISNER, M.D. and HOWARD MAHORNER M.D. F.A.C.S.,
New Orleans, Louisiana

UNILATERAL exophthalmos appearing as an early sign of hyperthyroidism is not rare. It is very likely that the first physician to whom such a patient applies for help will be an ophthalmologist and several of the patients in our series were first seen by ophthalmologists who suspected the presence of thyrotoxicosis. Other such patients however apply to their family doctor for diagnosis. Exophthalmos either unilateral or bilateral occurring as the first sign of hyperthyroidism and preceding other clinical and laboratory manifestations of hyperthyroidism occurs often enough for any examining doctor to keep this possibility in mind. Unilateral exophthalmos may be the only sign of incipient toxic diffuse goiter and may precede by months all other subjective and objective findings.

Unilateral exophthalmos may be caused by many conditions but unless the cause is otherwise obvious hyperthyroidism should always be considered. Dixon believes that thyrotoxicosis is a relatively common cause of mild unilateral exophthalmos which he says is almost always retraction only of the upper lid and no other abnormality. Other causes of unilateral exophthalmos as pointed out by Davis and Martin are intraorbital inflammatory disease either primary or secondary to an infected paranasal sinus, paralysis of the extraocular muscles, cavernous sinus thrombosis, congenital anatomic defects, angomas or aneurysm either within or behind the orbit. Of these vascular lesions and tumors are the most frequent causes of unilateral exophthalmos.

Cavity mentions that the term exophthalmos is often used loosely and sometimes is confused with a retraction of the upper lid simulating a protruded eyeball (Dalrymple's sign). He be-

lieves that many cases of unilateral exophthalmos are simply incomplete in terms of bilateral involvement. Not only is this true but also many cases of bilateral exophthalmos show some difference of proptosis in the two eyes. Most cases of unilateral proptosis in thyrotoxicosis will be provided the disease process is not checked eventually show similar changes of the other eyeball. Ruedemann explains the apparent unilaterality of exophthalmos under these circumstances as follows. He thinks the eyes are usually in a normal anterior posterior position with retraction of the lid on one side and with a partially successful attempt of the orbicularis palpebra to overcome the levator spasm of the other side. In his series of cases of real exophthalmos in hyperthyroidism the condition was always bilateral.

Cavity reported 3 cases in which unilateral exophthalmos was the first sign in Graves' disease and the diagnosis was not established until after intervals of 6, 8 and 20 months respectively. Ellett reported 2 cases with unilateral exophthalmos as the presenting sign and symptom in Graves' disease. His second case had a normal basal metabolism and exploratory operation was performed with removal of tissue from the muscle cone of the orbit. This was reported to be an epithelial like medullary tumor infiltrating the orbital fat. An orbital decompression was done according to Ellett and only hypertrophied extraocular muscles found. Two years later this patient had symptoms of hyperthyroidism and the basal metabolic rate was plus 46. This case and 1 in our series emphasize the fact that unilateral exophthalmos may appear as an early sign in thyrotoxicosis when no other signs or symptoms are present. The possibility of misdirected surgery on the eye under such circumstances is obvious.

The cause of exophthalmos in Graves' disease is still obscure. Within recent years many

investigators including Shockart, Loch and Friedman, Pochin Paulson, Arid and others have demonstrated that thyrotropic hormone from the anterior pituitary gland when injected into guinea pigs will produce exophthalmos. Dohyns has shown that thyroidectomy alone will cause increased prominence of the eyes in guinea pigs. Pochin in his studies found no difference in the prominence of the eyes between the thyroidectomized and the nonthyroidectomized guinea pigs following injections of the thyrotropic hormone. Dohyns studied the exophthalmos producing effect of several different preparations of thyrotropic hormone and in addition the effect of the presence or absence of the testes and the thyroid on the development of exophthalmos. He found that antuitrin T caused exophthalmos in guinea pigs. A crude thyrotropic product produced both thyroid hyperplasia and exophthalmos whereas a purified product produced only thyroid hyperplasia. Dohyns also found that orchidectomy had no inhibitory effect on the exophthalmos produced by the thyrotropic hormone.

Naffziger has shown that exophthalmos after thyroidectomy may become progressive a fact noted by many observers. He reported such a case with the pathological findings. The exophthalmos was due to great volume increase in the extraocular muscles. This increase was not a true muscle hypertrophy but a result of fibrosis following edema. Rundle and Pochin in a study of the orbital tissues in thyrotoxicosis conclude that exophthalmos in Graves disease is accounted for quantitatively by an increase in bulk of the retrobulbar tissues. The increase was relatively greater in the eye muscles of which the average fat content was doubled in a series of 17 thyrotoxic cases. The changes are most marked in the levator palpebrae superioris muscle which is known to be responsible for lid retraction. Increase of fat in the orbital fibro-fatty tissues is, however, responsible for most of the increase in bulk. Arid defines malignant exophthalmos as the progressive and alarming proptosis which occurs in a small group of patients usually after thyroidectomy and in the presence of a low basal metabolic rate. In these cases he found the extraocular muscles to be en-

larged from three to eight times their normal size. Grossly the musculature of the orbital muscle cone is observed to be finer, pale and edematous. Various stages of degeneration were observed histologically with interstitial edema and proliferation of small round cells which showed a tendency to accumulate around blood vessels. Fibrosis appeared more dense and extensive in the advanced cases. Arid produced exophthalmos in guinea pigs by injection of the thyrotropic hormone and found the exophthalmos due to myopathy of the extraocular muscles. Smelser (20) produced experimental exophthalmos in thyroidectomized guinea pigs by injection of extracts of the anterior pituitary gland. His study revealed a hypertrophy of the orbital fat almost entirely due to an increase in the water content of this tissue. No change in the lipid content of the orbital fat was noted. There was also a marked increase in the water component of the muscles. Smelser (19) after further studies states that it is not clear whether changes in the orbit are primary causing exophthalmos or secondary resulting from it. He concludes that the hypertrophy of the extraocular muscles in guinea pigs with experimental exophthalmos produced by injection of anterior pituitary extract appears to be a sequence of the exophthalmos; however, there is some indication that the extraocular muscles are affected directly in the same manner as the fat. Smelser (19) points out that changes in the extrinsic eye muscles have been emphasized in the literature since the observations of Burch and Naffziger who noted hypertrophy of the muscles, marked edema, perivascular infiltration with round cells and many atrophic muscle fibers suggesting Zenker's degeneration.

Mulvany states that some cases of hyperthyroidism go for long periods of time without a definite diagnosis. He cites 2 cases of patients under his care for 6 and 10 years respectively with basal metabolic rates ranging from plus 15 to plus 40. He says without ill effects. In these cases Mulvany warns that removal of the thyroid may accentuate the exophthalmos by stimulating the pituitary gland.

It is our experience that immediately following thyroidectomy in such cases exophthalmos

UNILATERAL EXOPHTHALMOS AN EARLY SIGN IN THYROTOXICOSIS

Fig. 3. These 3 photographs of a patient who had had a thyroidectomy in January 1942 were made May 1942, February 1943 and March, 1944. The first photograph shows marked exophthalmos, chemosis of the conjunctiva, and edema of the lids. The second photograph shows that the exophthalmos and edema have subsided but ophthalmoplegia is the residual of long continued severe exophthalmos. The third photograph shows the result after a "tuck"

ingers and the basal metabolic rate was elevated plus 18. Thyroidectomy was performed in January 1943. The pathological report was hyperplastic thyroid with areas of lymphoid infiltration. Following operation the exophthalmos progressed. He was not seen again until 1946. During this period of 3 years the exophthalmos had become severe and he went to a medical group in an adjacent state. There a Naftziger operation was done. The right orbit only was unroofed. Following this both eyes receded. However osteomyelitis of the skull resulted with considerable loss of bone in the right frontotemporal region. His health is now good but he has a depression and bone defect in the right frontal area.

CASE 3. A white female aged 27 years was referred by an ophthalmologist to whom the patient had gone because of a left unilateral exophthalmos. This patient noticed a prominence of her left eye 4 months before reporting for examination. The prominence of her left eye had gradually increased and 2 months after she first noticed the condition of the eye she began to suffer from extreme nervousness and irritability with crying spells. The patient stated that she had been nervous all her life so the increase in nervousness did not alarm her as did the exophthalmos. She had lost no weight and had no other complaints. On physical examination the patient was so nervous she was constantly moving her limbs and body and interrupting the history taking by outbursts of almost hysterical laughter. There was a moderate degree of exophthalmos of the left eye and the thyroid gland was firm, smooth and slightly enlarged. There was a marked tremor of the extended fingers and the skin was warm and moist. The basal metabolic rate was plus 35. This patient was given 0.4 gram of

operation performed by Dr. William B. Clark. The strabismus has been obliterated and the motions of the eyes are perfectly synchronized. There are two lessons to be gained from these findings. First exophthalmos, even if severe, may subside after thyroidectomy even though a long period is required. Second, a "tuck" operation for squint is sometimes of benefit in ophthalmoplegia due to long continued exophthalmos of hyperthyroidism.

thiouracil daily for 3 weeks and then admitted to the hospital. During the second week of thiouracil therapy 10 drops of Lugol's solution was given 3 times daily. After 1 week in the hospital on Lugol's solution thyroidectomy was performed. The pathological report was hyperplastic thyroid. She made an uneventful recovery and when recently seen, 4 months after the operation was free of signs of hyperthyroidism and the unilateral exophthalmos had subsided.

CASE 4. A negro female aged 30 years was seen because of a swelling in her neck of 1 month's duration. On examination the patient was found to have a right unilateral exophthalmos, the thyroid gland was enlarged firm and smooth. There was no tremor or other findings of thyrotoxicosis. The patient had not noticed the prominence of her eye but stated she had been nervous for the past 4 months and had lost 15 pounds in weight. She attributed this to worry over the death of her child 4 months previously. A friend of the patient had noticed the prominence of the right eye for several months but did not know the exact length of time. This patient was prepared with thiouracil and Lugol's solution and thyroidectomy was performed in March 1946. She made an uneventful recovery and was last seen 3 months after the operation when the condition of the eye had not changed. Later information on this patient has not been obtained.

CASE 5. A white woman aged 59 years was seen by an ophthalmologist because of unilateral exophthalmos. When first observed by us this patient had the classical signs and symptoms of thyrotoxicosis. She did not know how long her eye had been prominent but her chief concern was the unilateral exoph

Fig. 1

Fig. 2

Fig. 1. Man aged 53 years with unilateral exophthalmos. For 4 months this was the only subjective or objective sign of toxic diffuse goiter which later manifested itself characteristically (Case 1).

Fig. 2. Patient with severe exophthalmos which began 1 year ago in her remaining eye (Case 2). She has moder-

tely severe systemic signs of hyperthyroidism. The right eye was removed 15 years ago under a diagnosis of sebaceous carcinoma—the accuracy of which diagnosis now becomes doubtful. The impression is that the exophthalmos of the right eye was an initial sign of a long latent hyperthyroidism.

may be more marked but as weeks and months pass the prominence of the eyes diminish and the eye returns to normal anteroposterior position much more surely than if the case is neglected and thyroidectomy deferred. In deed extreme exophthalmos after adequate thyroidectomy for toxic diffuse goiter rarely fails to improve no matter how severe it may be. The gradual subsidence may take months or as long as 2 years.

Numerous laboratory investigators in the past working with guinea pigs have demonstrated exophthalmos by sympathetic nerve stimulation. To date there has been no proof that this is a factor in the production of exophthalmos in humans although there are some who feel that the sympathetic nervous system plays a part in this condition. As evidence against the sympathetics playing a part in the production of exophthalmos Brain reported a case history of a patient suffering from paralysis of the ocular sympathetic outflow as a result of syringomyelia who later developed Graves disease and showed both exophthalmos and retraction of the upper lids.

The following 5 cases of unilateral exophthalmos with thyrotoxicosis were observed on our private services.

CASE 1. A 47 year old white female first noticed prominence of her left eye in January 1921. If any

other symptoms of hyperthyroidism were present at that time they were apparently overlooked. In October 1931 her left eye was removed and the pathologic report was small round cell sarcoma. The authors have been unable to locate the original pathologic sections. Following the operation the patient was given radium treatments. Fourteen years later she was first seen by us. At that time she noticed her right eye becoming prominent and she began to complain of nervousness. Examination by the ophthalmologist failed to disclose any cause for the exophthalmos. The basal metabolic rate was plus 34. The patient's symptoms were mild but consistent with the diagnosis of hyperthyroidism. She did not report back until April 1946 at which time she had a basal metabolic rate of plus 31. Thyroidectomy was advised but as yet has not been performed. It is probable that the small round cell infiltration in the orbit was the result of exophthalmos. In this patient apparently an initial sign of a toxic goiter which only became obvious years later was the then associated exophthalmos of the remaining eye.

CASE 2. A 51 year old white male was seen by an ophthalmologist in July 1912 because of a left unilateral exophthalmos of 7 months duration. He was referred to us and at that time the patient had no symptoms of thyrotoxicosis and the basal metabolic rate was normal. Physical examination was negative except for a left unilateral exophthalmos. It was suspected that the unilateral exophthalmos was an early and only sign of incipient hyperthyroidism. This, however, could not be substantiated at that time. The patient was seen again in December 1912 and a slight exophthalmos of the other eye was noted and the prominence of the left eye was more pronounced. The patient exhibited a slight tremor of his extended

The patient had not noticed the prominence of her eye but stated she had been nervous for the past 4 months and had lost 15 pounds in weight. She attributed this to worry over the death of her child 4 months previously. A friend of the patient had noticed the prominence of the right eye for several months but did not know the exact length of time. This patient was prepared with thiouracil and Lugol's solution and thyroidectomy was performed in March 1946. She made an uneventful recovery and was last seen 3 months after the operation when the condition of the eye had not changed. Later information on this patient has not been obtained.

CASE 5. A white woman aged 59 years was seen by an ophthalmologist because of unilateral exophthalmos. When first observed by us this patient had the classical signs and symptoms of thyrotoxicosis. She did not know how long her eye had been prominent but her chief concern was the unilateral exoph

thalmos. Thyroidectomy was performed. One year later the patient was examined. The basal metabolic rate was minus 16; she had gained 15 pounds in weight and the exophthalmos was improved. The patient was again seen 4 years and 8 months after the operation and the exophthalmos showed further improvement.

COMMENT

Some phases of the problem of exophthalmos in exophthalmic goiter are not clearly understood; some are debatable. The cause of exophthalmos is not established but from experimental studies made by the authors cited and others, it would appear that a factor in the anterior pituitary secretion has the property of producing exophthalmos and the same or a different factor has the property of inducing hyperplasia of the thyroid gland. The latter was observed in experimental work on dogs performed by one of us (Howard Mahorner). Whatever the exciting factor for exophthalmos the pathogenesis is not at all clear. Is the first effect a weakness of extraocular muscles, a contraction of Mueller's muscle or an edema of periorbital tissues, or does one of these changes precede another only to be replaced later as the cause of sustained exophthalmos? Overactivity of the orbicularis muscle of Mueller could be an early change; later edema of periorbital fat and edema and weakness of periorbital muscles could further enhance the process.

There is little doubt that in some cases of exophthalmic goiter the immediate effect of thyroidectomy on the exophthalmos is to make it worse. Some observers (Mulvany and Means) believe that the cases in which such an untoward effect is to be expected may be identified before operation. The identity Means says, is to be recognized in patients with exophthalmos and mild signs of hyperthyroidism and relatively low basal metabolic rates. Means goes so far as to advise that such cases be treated medically and that surgery is contra-indicated. This does not agree with our concept of what can be expected in subsidence of exophthalmos after thyroidectomy. Perhaps the general but erroneous impression exists that following thyroidectomy for exophthalmic goiter the exophthalmos immediately subsides. On the contrary even in cases with high basal

metabolic rates and exophthalmos, the exophthalmos is frequently a little worse in the weeks immediately after operation. Only after many weeks and months does the exophthalmos gradually subside and under these circumstances usually the eyes return to normal. After adequate thyroidectomy improvement of severe exophthalmos may be expected to continue to normal even though the time required for this accomplishment is over a year and up to 2 years. It is our impression that thyroidectomy is indicated for toxic goiter when the diagnosis is made even though the associated exophthalmos is accompanied by a basal metabolic rate which is not even moderately high.

Because of the long time over which improvement in exophthalmos after thyroidectomy may occur radical procedures such as the Nassziger operation should be deferred unless extreme proptosis greatly jeopardizes the sight of the eye.

Another interesting but little known fact concerning exophthalmos from exophthalmic goiter is that manifest strabismus resulting from ophthalmoplegia due to long sustained exophthalmos may be corrected after subsidence of orbital edema by a "tuck" operation. Figure 3 shows a beautiful surgical result obtained in such a case by Dr. William B. Charl-

SUMMARY

We have reported 5 cases of unilateral exophthalmos due to exophthalmic (toxic diffuse) goiter. In all of these cases the unilateral exophthalmos was a prominent—in some it was the only—feature of the disease noticed by the patient.

A discussion of the causes and some of the clinical features of exophthalmos due to toxic goiter is presented.

THORACICOABDOMINAL APPROACH TO THE UPPER ABDOMEN

FRED R. HARPER, M.D. F.A.C.S., Denver, Colorado

THE organs of the left upper abdomen have always been difficult surgical problems because of lack of proper exposure. In working through an abdominal approach the surgeon is handicapped because the costal arch prevents adequate retraction. On the other hand an approach through the lower part of the chest necessitates reaching through the diaphragm to operate in the abdomen.

The approach that I am suggesting combines the thoracic approach with an abdominal approach. Adequate exposure is obtained by splitting the diaphragm. The incision is applicable for operations on esophagus, cardiac end of stomach, total gastric resections, diaphragmatic hernia, splenectomy, and vagus section when it is necessary to combine vagus section with gastroenterostomy.

The patient is placed on the table with the left side of the chest up in a true lateral position. The position is similar to the position used for posterolateral approach to the thorax. Intratracheal anesthesia is used. The incision is made over the ninth rib and extends from the angle of the rib across the costal arch and for about 2 inches into the abdomen. This brings the incision to the lateral border of the left rectus sheath. The ninth rib is removed from its angle to the costochondral junction. The thorax is entered through the bed of the ninth rib. At this point the pulmonary ligament is divided so that the lung falls away

from the diaphragm. The incision is then extended across the costal arch and for about 2 inches into the peritoneal cavity. The diaphragm is then split starting at the point where the costal arch was divided and extending the split in the diaphragm to the esophageal hiatus. Rib spreaders are then placed between the eighth and tenth ribs posteriorly. By opening the rib spreaders very adequate exposure is obtained from the aortic arch in the thorax to the duodenum in the abdomen. As shown in Figure 1 the exposure of the esophagus, stomach, and spleen is entirely adequate for any operative procedure involving these organs. After completion of the operation the diaphragm is sutured together with interrupted cotton mattress sutures.

In cases in which an esophagogastric anastomosis has been done the diaphragm can be sutured to the gastric side of the anastomosis at any desired level, thus leaving the stomach as an abdominal organ rather than transplanting it into the thorax. In such cases the phrenic nerve is crushed as it crosses the pericardium to prevent motion of the diaphragm postoperatively. After the diaphragm is sutured the incision is closed with interrupted cotton sutures with underwater drainage.

Postoperative course of these patients has been entirely uneventful. They have been ambulatory after 48 hours.

This approach has the following advantages:
 1. The exposure is more complete by this method than with either the abdominal or thoracic approach.

Fig. Drawing illustrating exposure of organs through the thoracoabdominal incision.

2 There is less danger of hemorrhage because the left gastric and the short gastric vessels can be divided under direct vision.

3 The diaphragm can be sutured at the desired level leaving the abdominal organs in the abdomen.

4 In the case of esophageal hiatus hernia the sack can be completely removed and also the abdominal organs can be explored at the completion of the operation.

5 In splenectomy adhesions of spleen to diaphragm can be separated under direct vision thus avoiding the danger of hemorrhage.

6 The patient suffers less shock because the plane of anesthesia is much lighter than is necessary for abdominal incisions.

7 The operating time is decreased because of the better exposure.

8 The convalescence is shortened because there is less danger of wound disruption in thoracic than in abdominal wounds.

In conclusion I have used this operation for carcinoma of the esophagus, total gastrectomy, splenectomy and diaphragmatic hernias and have found the operation to be entirely satisfactory.

HISTOPATHOLOGY OF THE ANAL DUCTS

GUY L. KRATZER M.D. and MALCOLM B. DOCKERTY M.D. Rochester, Minnesota

IN 1880 Herrmann and Defosses noted in the anal regions of human embryos certain channels lined with epithelium which emptied into the anal crypts. These tubules, which occurred in simple and in branched forms, were seen at times to penetrate the fibers of the internal anal sphincteric muscle. Their lining of low columnar dark-staining cells was distinctly different from the goblet cell investment of the rectum and the stratified squamous epithelial mantle of the anal canal. These pioneer investigators suggested the thesis that the tiny ductular 'recesses' that they described might play a rôle in the initiation and spread of infection around the anus. The anatomic and embryologic aspects of their work were confirmed by Johnson, Lockhart Mummery, Harris, Tucker and Hellwig and Pope to name a few. Lockhart Mummery expressed the belief that these ducts were vestigial remnants of the sexual scent glands of lower animals but he could not ascertain their function in human economy. Observing that sometimes they terminated blindly in the ischiorectal fossa, he suggested that they were potential avenues for the lateral spread of anal infections.

Tucker and Hellwig remarked on the paucity of these ducts in the human subject as compared with the number found in certain other animals. In a comparative embryologic study they detailed various modifications of the cells lining the ducts from the anus outward through the internal anal sphincter. They related the origin of certain anal fistulas to a primary infection in and about the anal ducts. In 1933 Pope described the presence of acinus-like buds in connection with the aforementioned structures. In 1936 Bremer noted the postnatal disappearance of secretory cells from the anal ducts in human beings. He ob-

served that usually not more than eight such ducts are to be found in any one rectum. In the same year Morgan observed that most of the ducts had their orifices in the posterior portion of the anal canal.

Briefly then, columnar lined epithelial ducts (anal ducts) are reported to exist in certain lower animals and in man. Their connection with the anal canal, their course through the internal anal sphincter and their blind termination reaching at times as far as the iliae fossa have placed them 'under suspicion' as avenues of perianal spread of infection. The present study was undertaken with a view to verifying or disproving certain statements relating to the incidence, position and significance of the anal ducts.

MATERIALS AND METHODS

The apparently normal anal canals of a number of human embryos and of one male stillborn infant were secured for study of the developmental aspects of the ducts. For comparative anatomic studies similar material was obtained from 10 monkeys. For the study of possible early inflammation in anal ducts of human adults 100 specimens were selected in which removal of the rectum and anus had been performed because of sigmoidal or rectosigmoidal lesions. Finally the slides made during a previous study of 100 cases of cryptitis in the human subject were reviewed to check on the presence of associated anal ducts and their possible rôle in the spread of anorectal inflammation. In each instance blocks were selected so as to include the mucosa of the rectum as well as of the anus. In the case of the male stillborn infant serial sections were prepared from a block including the entire circumference of the bowel. In the case of the human embryos sections were semi serial. With the rest of the material the blocks taken were sufficient in number to yield the desired information. All blocks of tissue were embedded in paraffin, sectioned in the usual manner and stained routinely with bema-

Abridgement of thesis submitted by Dr. Kratzer to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in pathology.

toxylin and eosin. When demonstration of the presence or absence of mucus was necessary the Galantha method of staining this substance was employed.

FINDINGS

A Male stillborn infant (eight months)
Serial sections of anorectal region Detailed study of 429 consecutive transverse sections revealed a total of 5 ducts, 2 of which were located in the anterior and 3 in the posterior half of the circumference of the bowel. The upper 312 of these sections were made through the rectal mucosa and in these no anal ducts were found, indicating that the direction of their penetration was not upward. The next 117 sections all showed one or more ducts, the openings of which were seen to be located at the level of the anal crypts where the mucosa of the bowel showed stratification of low columnar epithelium. The lining of the ducts was similar to that of the crypts. From 1 to 5 ducts were visible in each of these 117 sections and on 24 occasions actual penetration of the internal anal sphincter muscle was found to

Fig. 2. Same duct as shown in Figure 1. At this level the duct has penetrated the sphincter muscle (hematoxylin and eosin $\times 65$).

have occurred. In 42 sections the distal portions of the ducts were seen beneath a mucosal mantle of stratified squamous cells, indicating that the direction of ductular growth was away from the mucosa and downward. Moreover studies based on reconstruction showed their course to be irregular and even sinuous rather than direct, as was formerly believed. Definite lumina could not always be demonstrated probably as a result of tangential sectioning. In one duct there was a suggestion of an acinus-like bud with a single line of cuboidal epithelium. The lowest sections included perianal skin showing sweat glands, some of these being of the apocrine type. However these sweat glands were not easily confused with the anal ducts described previously. Rarely did the two types appear in the same section.

B Study of human embryos Seven human embryos varying in length from 1.5 to 14.5 centimeters were obtained and from 4 to 8 small blocks of tissue were removed from the anorectal region of each. Slides from these prepared and studied in the usual way revealed

ductal structures similar in appearance and distribution to those described previously in 3 cases each from a fetus more than 10 centimeters in length. No acinar budding was observed (Figs 1 and 2).

To check further on the efficacy of "random" sections as a means of determining the number and location of these anal ducts 6 additional human embryos (3 male and 3 female) were studied in a similar manner. However in this latter series the locations of the blocks were oriented as to their position on the specimen whether anterior or posterior. The entire circumference of the anorectal region was thus included in the blocks which were then sectioned serially. Every twenty-fifth section was preserved, stained, and mounted for study. Results are shown in Table I. One to 5 ducts were found in the posterior segments in all 6 cases. In only 3 were ducts seen in slides from the anterior segments. No sex difference was observed in relation to incidence or location of anal ducts.

C. Study of anorectal regions of 10 monkeys
Tissues fixed in formalin were obtained from the anorectal regions of 10 monkeys. The animals in question had been killed in the course of experimental studies and they did not exhibit gross evidence of disease of the terminal portion of the bowel. From each specimen two blocks of tissue were removed for sectioning, one from the anterior and one from the posterior portion of the anorectal region. In each instance the level of the anal crypts was selected on the basis of the findings cited in the

Fig. 3. Normal anal duct from an embryo. The section, which was taken near the blind extremity, shows a lining of several layers of cuboidal epithelial cells (hematoxylin and eosin $\times 395$).

foregoing. From each block two sections were made, one being stained with hematoxylin and eosin, the other with a stain for mucus.

In 10 preparations from 5 of the animals anal ducts were not observed—a finding which does not surprise us considering the nature of the sampling. Ducts were observed in tissue from the remaining 5 monkeys. Proximally as in the human material, these ducts were lined by 4 or 5 layers of transitional epithelial cells which appeared to be more like low columnar than squamous cells. Distally a double layer of cuboidal epithelial cells was noted. Penetration of the surrounding muscle was found to be present in 2 and absent in 3 specimens. In 1 case mild periductal inflammatory infiltration with lymphocytes was noted. No acini were found but the mucicarmine stain gave a positive reaction in isolated regions of each duct, confirming our assumption that the lining cells were entodermal rather than ectodermal. The ducts in each specimen numbered less than 5, with a 2:1 predilection for the posterior half of the anal canals.

Fig. 4. Anal crypt showing cryptitis. The ducts are shown with the transitional type of lining seen usually at their orifices. Subcutaneous periductal inflammation is present with many plasma cells (hematoxylin and eosin $\times 9$.)

D Histopathologic study of 100 normal (?) anal crypts from human subjects These crypts were considered more or less normal even though the rectum and anus had been removed for carcinoma of the rectosigmoid. In any event no gross evidences of anorectal disease processes were present. From each specimen one block of tissue was taken in such a manner as to include an anal crypt. In the original material it was seldom possible to satisfy our desire to select a posterior crypt inasmuch as orientation on the specimen was out of the question. However taking this into account it was interesting to note that one or more ducts were demonstrated by one microscopic section in no less than 55 of the 100 blocks which had been sectioned for study. Serial sections no doubt would have shown a much higher incidence (Fig. 3).

For information relating to the origin and cause of these ducts further sections were made on the 55 positive blocks and these sections were stained with hematoxylin and eosin and by the Galantha method for the demon-

Fig. 5. Anal duct in an adult. The lumen is filled with polymorphonuclear leucocytes and debris. A small duct may be seen with a few lymphocytes and considerable mucus (hematoxylin and eosin $\times 112$.)

stration of mucus. By means of this more or less random technique a definite origin of the anal ducts from a crypt was ascertained in 50 instances. In 33 slides the ducts were seen to penetrate the underlying muscle and a downward direction of growth was indicated in 11 sections wherein the epithelium overlying the deeper portions of the ducts was of squamous type. With minor variations the character of the epithelial lining of the ducts followed the pattern described in a foregoing paragraph. In 24 instances transitional columnar epithelium extended to the blind ends of the ducts. In 2 instances the proximal ends of the ducts were lined by stratified squamous epithelium. Results of staining for mucus were positive in 10 instances, the mucous cells appearing isolated or in small clumps scattered along the course of the ducts. No definite glandular acini were noted.

Of particular interest in this "normal" group was the presence in 13 cases of periductal inflammation. In 10 cases a chronic reaction was characterized by accumulations

of lymphocytes about the ducts, in 2 cases nests of plasma cells indicated the existence of a subacute inflammatory process and in 1 case an acute inflammatory reaction was noted with periductal accumulations of polymorphonuclear leucocytes and with edema of tissue. In no instance were the inflammatory cells located within the lumen of a duct. Cryptitis was associated in 12 of the 13 specimens in which there was periductal inflammation (Table II).

E. Review of some slides from cases of anal cryptitis incidentally showing anal ducts. In a previous study of 100 cases in which a gross diagnosis of cryptitis had been made ductular structures had frequently been noted. This material was again restudied and 24 specimens were selected as being pertinent to the present investigation. Of these 24 specimens 9 showed definite microscopic evidence of active cryptitis acute subacute or chronic as judged by the criteria outlined in section D. In 8 of

these 9 cases an associated periductal inflammatory process of corresponding type was observed (Fig 4). In 1 instance only did the inflammatory process seem to spread solely within the lumina of the involved ducts (Fig 5). Two specimens showed periductal inflammation in the absence of cryptitis (Table III).

COMMENT

In order to understand the possible importance of the anal ducts as avenues for the spread of anorectal infection one must realize the fact of their existence. The present study emphasizes that fact. These ducts are few and small. When they appear in the chance section made from the anorectal region, they may seem to be insignificant tubules having no apparent connection with the anal mucous membrane. Yet, as has been shown, their peregrinations through the internal anal sphincter theoretically expose such remote locations as the ischioanal fossae to the dangers of anal infection through their lumina or their periductal lymphatics. Therein lies their main interest, since this and other studies have not attributed to them any useful function in man.

Their relation in point of origin to the anal crypts is perhaps of some significance from the standpoint of infection (1-3 5 9 11 14 16). In the present study periductal inflammation seemed to be definitely related to the coexistence of cryptitis. The discovery of cases wherein the crypts were normal and the ducts inflamed perhaps signified a condition of residual infection which had previously existed also within the crypts.

Are the anal ducts important in the production of anal fistula? The present study while not answering this question, has

haps significantly confirmed the notion that the openings of the majority of the anal ducts lie posteriorly to the anus in the zone where anal fistulas are prone to develop. This phase of the problem needs further investigation.

SUMMARY

The present study has amply confirmed previous observations that epithelium lined ducts are to be found in monkeys, human embryos and human adults. Although few they may be demonstrated rather easily in about 50 per cent of human anal canals. From openings in the anal crypts (most often posterior) they course outward and downward often penetrating the internal anal sphincter. The majority are lined by transitional epithelium but definite mucus-producing cells may be demonstrated in 10 per cent of their linings. About 24 per cent of these ducts show focally or diffusely a periductal inflammatory reaction. When ducts are found in cases of anal cryptitis this incidence of periductal inflammation reaches 89 per cent. These ducts, we feel provide possible pathways for the lateral spread of such periductal infection once the latter is established, and it is conceivable that ischioanal abscess might have such a patho-

genesis. Equally possible etiologically is the development of anal fistula, the problem of which for the posterior portion of the tract corresponds to the principal site for the openings of the anal ducts.

EXTRA-ARTICULAR REPAIR FOR RUPTURED COLLATERAL AND CRUCIATE LIGAMENTS

EMIL D W HAUSER, M D F A C S Chicago, Illinois

ANATOMY

THE cruciate ligaments of the knee are two intra articular ligaments that stretch between the tibia and femur and cross each other between their attachments. The anterior cruciate ligament extends obliquely upward and backward from the space in front of the intercondylar eminence of the tibia to the back part of the medial side of the lateral femoral condyle. The posterior cruciate ligament passes from the back of the tibial spine forward and inward to the intercondylar surface of the medial femoral condyle. The anterior ligament prevents the tibia from being displaced forward on the femur. The posterior ligament prevents backward displacement of the tibia on the femur. Both cruciate ligaments are fairly tense in all positions. The anterior is under more tension with extension of the knee while the posterior has increased tension with the knee in flexion. They act jointly to prevent anterior and posterior displacement of the tibia and also to limit the rotation of the tibia that occurs with flexion of the knee.

PHYSIOLOGY

The action of the cruciate ligaments is dependent on the action of the muscles that control the knee and also to a great extent on the presence of satisfactory collateral ligaments. The cruciate ligaments act as check ligaments and work in conjunction with the collateral ligaments. They are dependent on the action of the quadriceps femoris muscle to give stability to the knee joint. A tear of the anterior cruciate ligament is not necessarily attended by loss of stability of the joint. A torn cruciate ligament has been established at operation without any instability of the joint. Studies on the cadaver have shown that the cruciate ligament may be divided without disturbance of function. However a torn cruciate ligament in the presence of a weak quadriceps femoris muscle will show some instability of the knee joint and lateral and posterior instability of the knee is always present when the tibial collateral ligament is divided along with division of the anterior cruciate ligament.

MECHANICS OF TRAUMA

The anterior cruciate ligament is torn as the result of abduction or hyperextension of the knee. When sufficient force is exerted to rupture the cruciate ligament the tibial collateral ligament is also torn. The characteristic finding of a torn anterior cruciate ligament is the so called drawer sign with the knee flexed the tibia can be displaced forward on the femur. At the same time the force could result in a tear of the medial meniscus and more extensive involvement would include a depressed fracture of the outer tuberosity of the tibia.

It is not uncommon to overlook the tear of a cruciate ligament, because of the recognition of the more obvious injury to the medial meniscus and the fracture of the tibia. The tear of the quadriceps fibers is apparent in those cases where an exploration is made to repair the tibial collateral ligament. The torn muscular fibers may be in the deeper part of the muscle. The tear of the posterior cruciate ligament occurs when the tibia is forcefully displaced backward on the femur tending to cause a posterior dislocation of the joint. The clinical sign is the excessive backward mobility of the tibia on the femur. The posterior cruciate may be torn without serious injury to a collateral ligament, and frequently there is no disability.

CONSERVATIVE TREATMENT

The treatment of a rupture of the cruciate ligaments is dependent on early recognition. If the joint is immediately immobilized in extension with the torn fibers intact, they can unite. In case the anterior cruciate is torn

a Posterior cruciate b Anterior cruciate c External cruciates

Fig. 1. Diagrammatic sketch comparing normal ligaments to reconstructed ligaments of the knee.

with the knee slightly flexed, the tibia is pushed backward and a cast is applied from the groin to the toes. Where the posterior cruciate ligament is torn the tibia is pulled forward on the femur and the extremity is fixed with a plaster of paris cast. The fixation should be retained for 2 to 3 months. Exercises of the quadriceps femoris are started immediately.

When a collateral ligament is torn fixation will allow healing. In those cases in which the meniscus is involved removal of the ruptured meniscus should be carried out and the torn tibial collateral ligament repaired at the same time. In the case of a depressed fracture of the tibia, adduction and compression should be carried out in an attempt to reduce the fracture. Here again fixation in extension by means of a cast to allow healing of the ligament is essential. Early activity of the quadriceps femoris must be urged and the return of normal function and active weight bearing instituted as soon as the symptoms have subsided. Where there are symptoms of instability or if the quadriceps is weakened re-

habilitation of this muscle will often give stability to the knee. In cases where the lateral collateral ligament is not repaired the gait can be great.

OPERATIVE TREATMENT

Many operations have been devised to construct cruciate ligaments from fascia or tendons. The results of intra articular operations have not been entirely satisfactory. Watson Jones reports recurrences after has elapsed. This is a difficult task. It can hardly be expected that the repair of the cruciate ligaments would give a satisfactory result where the tibial collateral ligament remains ineffective. On the other hand, a simple repair of the tibial collateral ligament does not always result in relief of the symptoms when the cruciate ligament is also torn (Carpbell). Since the tibial collateral ligament has been torn and stretched over a long period of time the structures are very weak therefore a shortening of this ligament after the manner of Mauck would not be adequate and supplementary tissue is necessary.

Fig. 1. A, Anteroposterior view of anatomical subject with division of tibial collateral and cruciate ligaments showing separation of the medial condyle from the tibia. B, After tendon transplant, showing decrease in the gap between the tibia and the medial condyle. C, Lateral view of anatomical subject with division of the tibial collateral and cruciate ligaments, showing posterior displacement of tibia on femur (positive "drawer sign"). D, After tendon transplant, showing normal relationship between tibia and femur with attempt to displace the tibia posteriorly on the femur (negative "drawer sign").

AUTHOR'S METHOD

The tendon of the quadriceps femoris offers a tissue that is strong and easily obtained and one of its attachments may be retained. A strip $\frac{1}{2}$ inch wide and about $2\frac{1}{2}$ inches long is made from the medial side of the tendon of the quadriceps femoris (Fig. 1 a). The proximal end is divided. The distal attachment is dis-

sected so that it remains attached only to the upper end of the patella. The proximal end is then reflected downward and attached on the medial and posterior side of the tibia. In this way a strong fibrous band passes obliquely from the anterior part of the knee at the level of the condyle to the posterior part of the tibia in the same direction and has the same effect

Fig. 1. 1. Skin incision operation, old scar excised. 2. Diagrammatic sketch of the ligaments of the knee. A. Medial collateral ligament. B. Ligament of the patella. C. Cruciate ligament. D. Cruciate ligament (in this case 1 and D are for 1). 3. Diagram showing the source of transplants.

a an anterior cruciate ligament except that in this case it is outside the joint. It also is a strong ligament on the medial side of the knee re-enforcing the tibial collateral ligament. The transplant is fastened directly to the bone through an incision in the periosteum; the periosteum is turned back by means of an osteotome and direct contact is thus obtained between the transplanted part and the bone. The attachment can be made by using a nail or still better a staple. The ligament is held in place by means of mattress sutures of chromic No. 1 catgut passed from the periosteum through the transplanted part of the tendon. A good stable ligament is thus obtained.

In cases of severe tears further repair may be made by transplanting part of the ligament of the patella (Fig. 1 h). A 1/2 inch strip is made from this ligament on the medial side. This is dissected free and separated from its

attachment to the patella. The proximal end of the ligament is then transplanted primarily in the region of the medial surface of the lower end of the femur and attached to the fascia in this area. The proximal end of the patella has the advantage that it is in the direction (see illustration) of the anterior cruciate ligament and at the same time it further re-enforces the weakened tibial collateral ligament.

A torn collateral ligament when repaired gives a weakened structure on the medial side of the knee and at the same time it prevents the function of the quadriceps femoris muscle in that area. The repair of the transplant from the tendon of the quadriceps femoris restores a functional attachment of the quadriceps femoris and activates the muscle in this area. The increased strength of the quadriceps is important in the restoration

Fig. 4. Transplant from the tendon of the quadriceps femoris muscle and the ligament of the patella. Inset—shows source of fascia to cover gap

Fig. 5. Suturing.

function. In addition the transplant from the tendon of the quadriceps femoris muscle tends to activate the entire quadriceps muscle. The medial side of the muscle when the tibial collateral ligament is torn loses its function and becomes weak and powerless. With the repair by means of the tendon transplant the quadriceps power is restored and this increase in strength tends to stabilize the knee. The third advantage of this type of repair for a torn cruciate ligament is its oblique direction. The direction of the new ligament on the external surface of the knee is the same as that of the anterior cruciate ligament within the knee and thus acts as a check against excessive mobility. As can be seen from the illustration (Fig. 1 c) when the transplant from the tendon of the quadriceps femoris is in position and the transplant from the ligament of the patella is brought upward and posterior the ligaments cross to form a cruciate ligament on the external surface. This is suggestive of the action of the ligament but for clinical purposes it is more important that the repair of the tibial collateral ligament be emphasized. Next in importance is the increase in the ability to restore normal strength to the extensor

muscles of the knee. The operation is technically simple, is extra articular and excellent results have persisted.

In carrying out this procedure on an anatomical subject for demonstration we saw how a knee with definite instability which permits excessive abduction and internal rotation and also has a positive drawer sign was converted into a stable knee (Fig. 2 A and C). There was no possibility of abduction or excessive rotation nor displacement of the tibia, after the ligament had been transplanted (Fig. 2 B and D).

These principles for the torn cruciate ligament have been applied to 15 cases which have come under my observation. In the early cases of a torn tibial collateral ligament and a torn cruciate ligament fixation of the knee in extension with a plaster cast was carried out. Exercise for the quadriceps muscle was started immediately weight bearing was started as soon as was possible without pain. The removal of the cast was followed by exercises of the extensor muscles of the knee. The patient was not permitted to return to work until the extensor group could carry out normal function. In this way instability and later develop-

an anterior cruciate ligament except that in this case it is outside the joint. It also is a strong ligament on the medial side of the knee re-enforcing the tibial collateral ligament. The transplant is fastened directly to the bone through an incision in the periosteum; the periosteum is turned back by means of an osteotome and direct contact is thus obtained between the transplant and the bone. The attachment can be made by using a nail or, still better, a staple. The ligament is held in place by means of mattress sutures of chromic No. 1 catgut passed from the periosteum through the transplanted part of the tendon. A good stable ligament is thus obtained.

In cases of severe tears further repair may be made by transplanting part of the ligament of the patella (Fig. 1, 3). A $\frac{1}{2}$ inch strip is made from this ligament on the medial side. This is dissected free and separated from its

attachment to the patella. The proximal end of the ligament is then transplanted proximally in the region of the medial surface of the lower end of the femur and attachment is made to the fascia in this area. The ligament of the patella has the advantage that it is in the direction (see illustration) of the anterior cruciate ligament and at the same time it further re-enforces the weakened tibial collateral ligament.

A torn collateral ligament when repaired gives a weakened structure on the medial side of the knee and at the same time it prevents the function of the quadriceps femoris muscle in that area. The repair of the transplant from the tendon of the quadriceps femoris restores a functional attachment to the quadriceps femoris and activates the muscle in this area. The increased strength of the quadriceps is important in the restoration of

Fig 4. Transplant from the tendon of the quadriceps femoris muscle and the ligament of the patella. Inset—shows source of fascia to cover gap

Fig 5 Suturing

function. In addition the transplant from the tendon of the quadriceps femoris muscle tends to activate the entire quadriceps muscle. The medial side of the muscle when the tibial collateral ligament is torn loses its function and becomes weak and powerless. With the repair by means of the tendon transplant the quadriceps power is restored and this increase in strength tends to stabilize the knee. The third advantage of this type of repair for a torn cruciate ligament is its oblique direction. The direction of the new ligament on the external surface of the knee is the same as that of the anterior cruciate ligament within the knee and thus acts as a check against excessive mobility. As can be seen from the illustration (Fig 1 c) when the transplant from the tendon of the quadriceps femoris is in position and the transplant from the ligament of the patella is brought upward and posterior the ligaments cross to form a cruciate ligament on the external surface. This is suggestive of the action of the ligament, but for clinical purposes it is more important that the repair of the tibial collateral ligament be emphasized. Next in importance is the increase in the ability to restore normal strength to the extensor

muscles of the knee. The operation is technically simple, is extra articular and excellent results have persisted.

In carrying out this procedure on an anatomical subject for demonstration we saw how a knee with definite instability which permits excessive abduction and internal rotation and also has a positive drawer sign, was converted into a stable knee (Fig 2 A and C). There was no possibility of abduction or excessive rotation nor displacement of the tibia after the ligament had been transplanted (Fig 2 B and D).

These principles for the torn cruciate ligament have been applied to 15 cases which have come under my observation. In the early cases of a torn tibial collateral ligament and a torn cruciate ligament fixation of the knee in extension with a plaster cast was carried out. Exercise for the quadriceps muscle was started immediately, weight bearing was started as soon as was possible without pain. The removal of the cast was followed by exercises of the extensor muscles of the knee. The patient was not permitted to return to work until the extensor group could carry out normal function. In this way instability and later develop-

Fig. 2. (a) Anteroposterior stability of the knee. (b) Lateral stability of the knee.

ment of arthritis of the knee was prevented. In the early cases that required surgery the torn collateral ligament was repaired. In the older cases where there was very little instability but an uncertainty and a drawer sign with the knee relaxed, exercises for rehabilitation to full strength of the quadriceps muscle were sufficient to rest in normal function and cure the cause of the patient's complaints. Where there was instability and signs of a definite tear of the tibial collateral ligament surgery was advised. Since this latter type of case is most difficult and most important a case report is included.

REPORT OF CASE

The patient was a 43-year-old husky man who complained of pain, weakness, and swelling in the left knee with instability. He had injured his knee in a plane crash during the first World War and it had been getting progressively worse. When he came to me there was a definite drawer sign and it interfered with his occupation as a truck owner and manager. A try-on of a brace after the injury the knee kept troubling him and in 1930 after a diagnosis of a fractured medial meniscus he was operated upon and the meniscus was removed. He was relieved of pain when the symptom recurred. He had a clicking again with instability of the knee as well as pain. A try-on of a brace relieved the pain and the lateral meniscus was removed. Some improvement followed but

until 1930 when there was a recurrence of a definite deal of instability. He could not play sports and was unable to take part in other sports. He prolonged standing the knee would ache and was painful. An attempt to swing a golf club with the knee into a rotary position caused a definite knee slipping out of joint (subluxation). The knee became swollen and remained so. He was examined by the surgeon who removed the swelling and was told that he had a torn cruciate ligament with instability of the joint. He was advised an operation for repair of the cruciate ligament since in the surgeon's experience such repairs had been unsuccessful. He was told to rest the knee and to avoid strain and if the knee continued to worsen the best treatment would be an arthroplasty of the knee.

General examination of the patient was normal in every way with the exception of the knee. His blood pressure was 100/65 and laboratory tests were normal. Physical examination of the knee showed definite instability. The knee could be brought out into valgus at an angle of 45 degrees when the knee was slightly flexed. When the knee flexed and the foot brought into external rotation any attempt to put weight on the knee caused definite subluxation. The tibia could be drawn forward as well as pushed posteriorly on the femur (positive drawer sign). There was definite thickening and increased fluid. The fat pad was palpable and thickened.

Diagnosis was made of a torn cruciate ligament. It had been expressed by the original surgeon. The chief difficulty was the instability of the knee and the weakened tibial collateral ligament. Surgery was advised.

At the time of operation the tibial collateral ligament was exposed and in some areas was as thin as paper. The medial side of the femur and the patella was traced out stretched, weak and ineffective. A tran plant was taken from the end of the quadriceps femoris muscle and secured anteriorly and posteriorly over the medial side of the knee. It was tensioned on the tibia directly into the posterior (Fig. 3). A second transplant was then taken from the ligament of the patella. In removing the ligament from the ligament of the patella the lateral part was exposed. It was found to be atrophied and showed signs of chronic inflammation and it was removed through this operation. A tran plant of the ligament of the patella was attached to the patella. The distal part was attached to the tibia (Fig. 4). The ligament was secured from the proposed operation to meet the extraordinary weakness of the ligament on the medial side of the knee. The ligaments in place there was still a weakness of the structures between the two ligaments. A fascia to cover this gap was obtained from the anterior part of the patella (Fig. 5). The aponeurosis was reflected and placed between

ligament made from the tendon of the quadriceps femoris muscle and the one made from the ligament of the patella. The ligaments were sutured with No. 6 chromic catgut. The attachments to the periosteum were held in place with chromic No. 1 catgut (Fig. 5). The result was a firm collateral ligament which prevented the knee from any abnormal lateral movement. In addition the transplant from the tendon of the quadriceps femoris brought into play fibers of muscle which previously were not effective. Furthermore the pull on the newly formed collateral ligament was in the direction of the posterior cruciate ligament so that posterior displacement of the tibia on the femur was not possible. The skin was closed with black silk in the usual manner and a compression bandage was applied. The fifth day after operation quadriceps exercises were started. He had an uneventful convalescence. His temperature rose to 99 degrees the first 2 days and then became normal and remained so. The sutures were removed on the twelfth day and he was up in a chair 2 days later. On the twentieth day he was walking and he left the hospital on the twenty fourth day. The exercises were continued to increase the strength of the quadriceps. He returned to work after 2 weeks and continued his exercises. When seen 4 months after operation he was able to come to a squat position with all his weight on the leg operated upon. He was able to play golf and has continued his occupation without any return of symptoms. When last seen 2 years after operation he still had complete recovery without any sign of recurrence. The knee was normal in size and appearance and firm atrophic fibrous bands were palpable under the skin. The knee was stable and he was able to do all his work without symptoms (Fig. 6).

SUMMARY

1 The symptoms of a torn cruciate ligament are dependent on the strength of the collateral ligaments as well as on the effectiveness of the quadriceps femoris muscle.

2 Torn cruciate and collateral ligaments will respond to early efficient conservative treatment.

3 Neglected cases of torn cruciate ligaments with weak stretched collateral ligaments, require surgical repair. For these cases an extra articular method of repair has been devised.

4 The author's operation is described. A section of tendon of the quadriceps femoris muscle is taken and division is made proximally the distal part being left attached to the patella. The proximal end of the section of tendon is then fastened to the posterior part of the upper end of the tibia. A section of the tendon of the patella about a centimeter in width can then be separated leaving the distal end attached. The free proximal end can then be transferred obliquely to be attached in the region of the condyle of the femur posteriorly. We thus have an extra articular cruciate ligament. More important is the fact that we have reconstructed a firm strong collateral ligament.

ANATOMIC DISARTICULATION OF THE HIP

HAROLD B. BOYD, M.D., F.A.C.S., Memphis, Tennessee

IN order to obtain an ideal stump which will close without tension and minimize shock incident to disarticulation at the hip joint, a technique has been developed by which the dissection proceeds along fascial planes and the muscles about the hip are divided at either their origins from the pelvis or their insertions into the femur.

This technique is in accord with principles advocated by Callander and Kirk. Callander has found that, for amputations just above the knee, detachment of the muscles from their insertions or at their points of origin is much less shocking than amputations through the muscles of the thigh. Kirk, in describing amputations at the hip states: "All muscles except those normally belonging in the buttocks are removed from the stump, saving one

From the Walter C. Campbell Clinic.

muscle flap which is conserved to fill up the acetabulum if a disarticulation is elected. The muscles on the whole are cut at their origin.

In the operation to be described, detachment of the muscles from their origins or insertions permits closure of the wound with ease and without tension. The large gluteal flap forms an excellent stump. A familiarity with the anatomy of the structures about the hip joint is essential.

This operation has been performed by members of the staff of the Campbell Clinic on patients, and has been employed successfully in one additional case by Dr. Van Doozer in Buenos Aires.

Technique. The extremity is elevated and, unless contraindicated, an elastic bandage is applied to express as much blood as possible from the leg and thigh into the systemic cir-

Fig. The stage of the anatomic disarticulation following ligation of the femoral vessels and nerves, and detachment of the sartorius, rectus femoris, pectineus, and iliopectineus muscles. Inset shows the line of the incision.

ulation. The bandage should not be wrapped over a malignant tumor as cells from the neoplasm might be forced into the general circulation. An Esmarch tourniquet is applied tightly about the extremity 2 inches below the level of the disarticulation. Unless the tourniquet is placed below the point of amputation the limb will refill with blood during the operation despite primary ligation of the femoral artery and vein. The blood coming through the anastomotic branches of the inferior gluteal artery with the medial femoral circumflex and highest perforating arteries.

The patient is placed on the unaffected side and after the routine surgical preparation sterile drapes are so applied as to permit free movement of the extremity.

A racquet type of incision is employed. Beginning at the anterior superior iliac spine, the

incision is curved downward and medially almost parallel with Poupert's ligament to a point on the inner aspect of the thigh 5 centimeters below the origin of the adductor muscles. Before proceeding farther the femoral artery and vein are isolated and ligated and the femoral nerve is injected with novocain and divided. The incision is then continued around the posterior aspect of the thigh approximately 5 centimeters distal to the ischial tuberosity and along the lateral aspect of the thigh about 8 centimeters distal to the base of the greater trochanter. From this point, it curves upward joining the original incision below the anterior superior iliac spine (insert Fig. 1). The sartorius muscle is now detached from its origin at the anterior superior iliac spine and reflected distally. The rectus femoris is detached from the anterior inferior iliac spine and also reflected distally and the

^a Died with metastasis

pectineus is divided approximately $\frac{3}{4}$ inch from the pubis. By externally rotating the thigh the lesser trochanter is brought into view. The iliopsoas tendon is then severed at its insertion and reflected upward (Fig 1). The adductor and gracilis muscles are next detached from the pubis and that portion of the adductor magnus which arises from the ischium is severed at its origin. The plane between the pectineus and the obturator externus and short rotators is delineated and the branches of the obturator artery are ligated. The obturator externus muscle is later detached from its insertion into the femur if the muscle is divided at its origin the obturator artery may be severed and retract into the pelvis, resulting in hemorrhage difficult to control.

The thigh is now rotated internally and the gluteus medius and minimus muscles are detached from their insertions into the greater trochanter and retracted upward. The fascia lata is divided below the insertion of the tensor fasciae latae muscle in the line of the skin incision together with the lowermost fibers of the gluteus maximus muscle and the tendon of the gluteus maximus is separated from its insertion into the linea aspera and retracted upward. The sciatic nerve is next injected with novocain and divided. The short rotators of the hip i.e. the piriformis, gemelli, obturator internus, obturator externus and quadratus femoris are divided at their inser-

tions into the femur and the hamstring muscles are then severed from the ischial tuberosity (Fig 2). The disarticulation is now complete except for incision of the capsule of the hip joint near the acetabulum, and division of the ligamentum teres.

From the description given, it will be observed that all the muscles are divided *distal to the bone* at either their points of origin or insertion and that the dissection proceeds *along the fascial planes*. All the arteries are clamped and ligated as they are encountered. Excessive bleeding during the operation is prevented by the initial ligation of the femoral artery above the profunda. The other major vessels which require ligation are the branches of the obturator artery and the inferior gluteal artery.

The disarticulation having been completed the gluteal flap is brought forward and its distal portions of the gluteal muscles are sutured to the points of origin of the pectineus and adductor muscles. The skin is closed in the routine manner. The gluteal flap is sufficiently large to permit closure without tension (insert Fig 2). A drain is placed in the inferior portion of the incision, to be removed after 24 to 36 hours.

Five of the 7 operations performed by the method were for malignant tumors of the femur: 1 was for a Charcot hip with a secondary infection and 1 was for a fibrosarcoma of the thigh. There were no operative deaths. Four of the patients died of metastases from 1 to 10 months later (Table I).

These same principles have been followed in disarticulation of the shoulder. The deltoid muscle was detached from its insertion and retracted upward and the other muscles about the joint were severed at their attachments to the scapula or humerus. It was not necessary to divide any of the muscles through their bodies. The deltoid flap fell into place, permitting an ideal closure without tension.

CONCLUSIONS

Disarticulation of the hip is, at best, a shocking procedure. It should not be undertaken unless blood is available for transfusion during the operation. Experience indicates that the method presented is accompanied by

less shock than the conventional type of disarticulation of the hip. Dissection is carried out along fascial planes, permitting the surgeon to isolate and clamp the vessels as they are brought into view. Detachment of the muscles in avascular areas, i.e. at their origins or insertions is a major factor in the prevention of excessive blood loss. The procedure is a little more time-consuming than those in

which the muscles are divided through their bodies though the expenditure of the additional time is well justified by the better post operative condition of the patient.

THE ADVANTAGES AND LIMITATIONS OF THIOURACIL THERAPY IN THYROTOXICOSIS

EDSON F FOWLER M.D. and WARREN H COLE, M.D. F.A.C.S. Chicago, Illinois

WHEN thiouracil was introduced by Astwood and other pioneer workers in this field the possibility seemed definite that no longer would there be need for surgical therapy in hyperthyroidism. However experience with the drug has revealed enough limitations to leave iodine a definite place in the treatment of hyperthyroidism. Nevertheless, the introduction of thiouracil and allied compounds can be considered epochal in the treatment of hyperthyroidism. Since several compounds are known to exert the same action on the thyroid as does thiouracil, it is of course likely that other drugs will be found which will be superior.

Reactions The reactions sustained by the patient during treatment with thiouracil represent one of the greatest disadvantages of the drug. In a study of 1,543 cases reviewed from the medical literature, reactions were noted in 13.8 per cent of patients treated. The most serious reaction was agranulocytosis which was encountered in 0.78 per cent of patients in the series reviewed. Although much less serious, leucopenia was more common being reported in 3.11 per cent. Vomiting, dermatitis, and pruritis were encountered in 2.9 per cent, 1.1 per cent and 4.5 per cent, respectively. A great variety of other reactions, including purpura, localized edema, arthralgia, swelling of the salivary glands etc. have been observed. The mortality rate, which in the series of 1,543 cases was 0.45 per cent and is as great as that in thyroidectomy for moderately toxic goiter would indicate a most serious disadvantage or limitation in the use of thiouracil.

In our series of 79 cases the reactions were similar but slightly higher in incidence than were those reported in the literature (Table I) although most of the reactions were relatively

insignificant. We encountered no cases of agranulocytosis, although marked leucopenia developed in 4 cases.

We noted very little correlation between dosage and duration of drug therapy although the most serious reactions were apt to occur early in treatment. It must be remembered however that agranulocytosis may develop at any time during the course of therapy. No death in our series could be attributed to thiouracil. One death occurred while the patient was being treated with the drug, but a pharyngeal abscess and pneumonia seemed to account for the fatality without thyroid being considered as a complicating factor. The patient did not have agranulocytosis, leucopenia or bone marrow changes.

Advantages and indications for the use of thiouracil In our estimation thiouracil has its greatest usefulness in the treatment of moderately severe toxic goiter in patients who are so toxic that preparation with iodine will not lower the hyperthyroidism to a degree sufficient to allow bilateral thyroidectomy safely. Thiouracil likewise is strongly indicated in patients who have cardiac failure secondary to hyperthyroidism as seen most commonly in toxic nodular goiter. Treatment over a period of several weeks invariably results in improvement of the cardiac status; the nutritional state likewise improves remarkably. In recurrent goiter and in mildly toxic goiter with a small gland, permanent remissions are obtainable in a large percentage of cases. In patients who are sensitive to iodine or have tuberculosis (in which disease iodine is supposedly dangerous) thiouracil is strongly indicated.

Disadvantages and limitations in the use of thiouracil The greatest disadvantage in the use of thiouracil is obviously the mortality rate produced by administration of the drug. Although we have not had any fatalities in our series which could be attributed to the use of the drug, the mortality rate in the 1,543 cases

From the Department of Surgery, University of Illinois College of Medicine and the Illinois Research and Educational Hospital, Chicago.

TABLE I.—TOXIC REACTIONS IN 79 CASES TREATED WITH THIOURACIL AT ILLINOIS RESEARCH HOSPITAL

Reactions were sufficiently serious to require cessation of the drug in 9 per cent.

reviewed (3) in the medical literature was 0.45 per cent. This one disadvantage is so serious that the drug can probably never be used with utter safety particularly since it is now being used with great care and only by a relatively few workers most of whom are making such a careful study of the drug that reactions are detected early. Even though the incidence of other reactions was 13.8 per cent, most of them can be considered as insignificant. The action of thiouracil is so slow that it literally takes weeks to eliminate the thyrotoxicity. This delay might be considered uneconomical and many patients as well as physicians may become impatient particularly since thyroidectomy can be performed in the mildly toxic goiter patient, with a very low mortality rate and with only 12 to 15 days of preliminary iodine therapy. In the presence of crisis the drug is dangerous and should not be given particularly since in this group of patients the effect is so slow that it would probably not decrease the mortality rate. Thiouracil produces increased vascularity of the thyroid gland thereby making the operation more difficult because of the additional hemorrhage encountered. The use of iodine for 10 to 12 days before operation, however, eliminates or minimizes this vascularity. Thiouracil does not produce a decrease in the size of the gland. Accordingly in toxic nodular goiter if the action is optimal and sustained so that operation is not indicated we still have to be concerned about the possibility of the development of carcinoma. The high incidence in a goiter belt of carcinoma in nodular goiter has been noted in a previous publication (2) and made the authors concerned as to the fate of patients with residual nodules after thiouracil

Fig. 1. Average response of hyperthyroidism to thiouracil. The basal metabolic rate was reduced from 60+ to 0 in 8 weeks, representing a drop of about one point in the metabolic rate for each day of therapy.

therapy. We have not, however, encountered any carcinomas in glands of patients treated with thiouracil and know of no such instances in the literature. Therefore we are of the opinion that the possibility of development of such a complication can be considered insignificant.

Dosage and response to thiouracil. We are using a dosage of 200 milligrams three times a day. The drug is maintained at this level for at least a few weeks and then dropped to one-third to one-half of this amount, depending upon the response of the patient. The patient must be watched at all times and leucocyte counts performed two or three times a week. Moreover the patient must be instructed to report all reactions regardless of severity or degree. Since severe reactions including severe agranulocytosis can develop at any time

TABLE II.—INDICATIONS OR ADVANTAGES OF THIOURACIL

1. Patients so toxic thyroidectomy not safe with iodine.
2. Mild toxicity with small gland. (Permanent remission in about half of this group.)
3. Recurrent thyrotoxicosis (following operation) with small gland.
4. Thyrocardiacs.
5. Patients sensitive to iodine or having pulmonary tuberculosis.

Fig. 2. Unusually rapid response to thiouracil which is perhaps explained for the most part by inaccuracy of the initial basal metabolic reading.

the fact that administration of the drug for 4 to 5 weeks has not resulted in reactions cannot be considered as an excuse for less critical observation. The danger of development of agranulocytosis is so unpredictable that the drug should be discontinued for 3 or 4 days before operation lest agranulocytosis develop on the day of operation and not be detected.

Reference has already been made to the desirability of giving iodine as Lugol's solution or iodide for 12 to 14 days preceding operation. This program will result in a great decrease in vascularity and the operation is thereby made much easier.

Lahey and others have noted that there is regression of hyperthyroidism during thiouracil therapy to a degree equal to about one point in basal metabolic rate for each day of

TABLE IV—RESULTS AFTER DISCONTINUATION OF THIOURACIL

No. of Cases	Average Initial BMR	Average duration to normal BMR	Remissions?
10	65.3	7.5	No. Symptoms returned in 7 mos.
9	59.1	6.8	Yes. 8-7 mos after discontinued.
7	51.7	6.4	Yes. But only 1-3 mos. after discontinued.

BMR, Basal metabolic rate.

treatment. In an analysis of our patients we noted, however, that it took a period slightly longer than this to bring the patients to normal basal metabolic rate. In our 1 with toxic diffuse goiter it took an average of 8.8 days in addition to the one day per point basal metabolic rate, to bring the rate to normal. Patients with toxic nodular goiter respond somewhat more slowly than do those with toxic diffuse goiter. For example, in the toxic nodular group it took an average of 11.1 days longer than the one day per point basal metabolic rate for return to a rate.

Although failure of thiouracil to reduce toxicity is seldom reported in the literature, we have had 3 patients with hyperthyroidism in whom thiouracil was ineffective. It is well known, however, that if iodine has been given before thiouracil is started, the beneficial effect of the latter drug will be reduced markedly.

Remissions. The number of patients whom we have observed over a prolonged period of time for determination of the possibility of permanent cure or remission has been relatively small, namely only 26 cases. We have learned as have others working in this field that treatment for less than 6 months is not apt to produce a remission with any degree of permanency. With one or two exceptions of the patients in this series of 26 had taken the drug for 6 months or longer. Ten of them had recurrence within 1 to 7 months. It is somewhat difficult to determine exactly when a recurrence takes place, largely because the symptoms develop so insidiously that the patient is not entirely aware of the exact date of recurrence of symptoms. Nine of the 4 patients have had no recurrence of symptoms for 8 to 17 months (average 12.1 months) but

TABLE III—LIMITATIONS OR DISADVANTAGES OF THIOURACIL

1. High mortality rate (0.45 per cent in 1543 cases—Fowler)
2. Toxic reactions 13.8 per cent.
3. Slow action (uneconomical).
4. Useless in crisis (dangerous?).
5. No decrease in size of gland. (If remission permanent, is persistent gland dangerous—Carcinoma?)
6. Increases vascularity of gland,—thus adding to operating time and blood loss unless iodine is given.

Fig. 3. Unusually slow response to thiouracil. After 73 days of therapy the basal metabolic rate had receded only 5 points.

owing cessation of thiouracil therapy. Seven of the 26 patients have had no recurrence of symptoms but observation has been for a much shorter time namely only 1 to 5 months following cessation of therapy. In general we have found that patients with mild toxicity and those with relatively small glands are more apt to have a permanent remission than are other types of patients.

Determination of operability. In patients treated successfully with thiouracil it will rarely be necessary to make an appraisal of the patient's condition to determine operability or time for operation. However there will be a small number of patients who will have reactions following thiouracil and a few who will not respond to the drug thereby constituting an appreciable number of patients who must be treated by conventional methods consisting mainly of iodine and operation. It took us three or four decades to learn how to determine operability and optimum time for operation in thyrotoxicosis. The authors wish to make a plea that the profession not abandon all this information which required years for accumulation. All of us have certain pre-

Fig. 4. Deleterious effect of preliminary course of iodine on thiouracil response. Previous to 6 weeks' treatment with thiouracil the patient had received Lugol's solution for 8½ weeks. The 6 weeks period of treatment with thiouracil resulted in no reduction in basal metabolic rate although there was considerable weight gain and a slight decrease in severity of symptoms.

requisites to determine operability. Unfortunately not many have taken the time or trouble to convert these prerequisites into terms that can be transmitted to others. From a teaching standpoint, we have learned that to transmit information of this type to students, it must be converted to mathematical status or its equivalent. We have utilized the pre-

TABLE V.—PREREQUISITES FOR BILATERAL THYROIDECTOMY IN TOXIC GOITER

1. Gain in weight and strength.
2. Resting pulse below 110.

4. Response to iodine or thiouracil.
5. No untreatable complications.

During operation: If pulse rate goes to 135 not explainable on basis of anesthetic, consider possibility of removing only one lobe. If pulse rate goes above 145, indications are to stop the operation or remove only one lobe.

requisites in determination of safety for bilateral thyroidectomy in toxic goiter (Table V)

The surgeon has the opportunity to save many lives by asserting good judgment in the operating room. For example, as suggested in Table V if the pulse rate goes to 135-140 unrelated to anesthesia, it is obvious that the patient was more toxic than the surgeon anticipated; therefore he should consider the possibility of removing only one lobe. On the other hand if the patient's pulse rate goes to 145 or higher during the operation without relation to the anesthesia, the surgeon should consider stopping the operation at once or at least removing only one lobe. On many occasions the authors have returned patients to the ward when they arrived at the operating room with a fast pulse which did not settle down under anesthesia. If the pulse rate does not come down to 130 or thereabouts under anesthesia the incision should be delayed; it may be wise to cancel the operation and wait several days for a more opportune time. This decision is particularly indicated if an excess amount of oxygen seems to be required during the anesthetic, and if there is difficulty in eliminating cyanosis.

SUMMARY

Thiouracil has been of great assistance in the treatment of hyperthyroidism. It will reduce the basal metabolic rate to normal in at least 95 per cent of patients with hyperthyroidism except that reactions may prevent continuation of the drug (in 9 per cent of our series). A survey of the literature reveals an incidence in reaction of 13.8 per cent. Agranulocytosis occurred in 0.78 per cent of patients (1543 cases studied from the literature, with a mortality rate of 0.45 per cent). Besides agranulocytosis, reactions consisted of leuco-

penia, nausea and vomiting, dermatitis, pericarditis, fever, swelling of the salivary gland, arthralgia and other minor complaints. In a series of 79 patients, reactions were slightly greater in number but of less severity than noted in the literature. We had no deaths attributable to thiouracil.

The greatest advantage of thiouracil over iodine is in the group of patients who are so toxic that bilateral thyroidectomy is contraindicated under iodine therapy. The drug is particularly useful in patients with cardiac decompensation secondary to hyperthyroidism. Experience about one half of the patients treated will have remission of prolonged or permanent type but these patients must be watched. Patients with mild toxicity and small glands are more apt to have permanent remission than are other types. Patients with toxic diffuse goiter respond slightly better than those with toxic nodular goiter.

The most serious disadvantage is the mortality and particularly the mortality rate. The slow action is uneconomical; many and internists feel that treatment of patients with mild hyperthyroidism with iodine and thyroidectomy may be superior to the thiouracil, particularly since the mortality rate of operation is so low in that group.

Since there are numerous drugs which produce cessation of hormone formation, it is likely that a better drug will be found which will not be toxic. A new drug, propylthiouracil appears to be much superior to thiouracil.

OBSERVATIONS ON THE USE OF G-11 IN THE SURGICAL SCRUB

C V SEASTONE M D Major MC AUS Madison Wisconsin

THE following studies were undertaken in the attempt to confirm the observations of Traub and others (3, 4) who have reported the remarkable effect of the compound G-11¹ (2,2'-dihydroxy-5,5'-bis(6-chloro-2,4,6-trichlorophenyl) methane) in reducing the resident flora of the skin. In general we have been able to substantiate these results, the data presented below indicate certain modifications in the methods of using and evaluating the material which may be employed to advantage.

Traub found that persons using for all skin washing purposes a soap containing 2 per cent G-11 showed very low numbers of skin organisms when tested by the Price technique (2). He states (4) that if the material is to be used in a surgical scrub it must also be employed exclusively whenever soap is used on the skin, application only at the time of the actual scrub would be ineffective, since a preliminary period of contact is required for the action of the disinfectant to appear. Such a requirement presents some inconvenience and more supervisory difficulty; the effectiveness of the agent has therefore been tested when its use was restricted to operating room procedure.

According to Traub there is no evidence for the carry-over of disinfectant into the medium to account for the low numbers of organisms seen in the tests. Since his evidence for this is only indirect, we have examined the possibility in greater detail. Moreover, since the basis for the activity of G-11 must be primarily chemical, the effect of eliminating the scrubbing brush from the surgical wash was investigated.

Method of determining numbers of skin organisms The technique was essentially that of Price as modified by Pohle and Stuart. The

individual to be tested wet his hands to a point 1 inch above the wrist joint in 1 liter of sterile distilled water in a sterile basin. Ivory soap was applied to the wet skin area for 25 seconds after which the subject massaged his hands thoroughly for 75 seconds. The hands were then rinsed in the basin for 25 seconds. Poured plates containing 0.1 and 1.0 milliliter of the thoroughly stirred basin water were prepared. Counts were made after 48 hours at 37 degrees C. The serial basin portion of the Price method was not used since the first basin which gives the highest counts analogous to the dose of micro-organisms released in the event of tearing a glove was our main interest. The skin counts reported here are expressed as the number of organisms per liter of wash water, or per basin.

Susceptibility of normal skin organisms to G-11 The plating medium in this experiment consisted of bacto-tryptose 10 per cent, bacto-beef extract 0.5 per cent, sodium chloride 0.5 per cent, and agar 1.5 per cent. A 1 per cent alcoholic solution of the monopotassium salt of G-11 was diluted serially in broth of the same composition as above. Organisms were tested both in broth and in agar. The stated concentrations of G-11 represent final concentrations in the medium. The strains employed were obtained from skin tests as described on two individuals who had gone through a thorough wash with plain green soap solution, and had worn sterile gloves for 45 minutes. They had not been in contact with G-11. Ten colonies were isolated from each, all 20 strains were staphylococci, either lemon yellow or nonpigmented. No gram negative forms were found. In testing G-11 in broth 5 milliliter amounts containing 10 fold dilutions of G-11 were inoculated with 0.1 milliliter of a barely turbid suspension of the test organisms made from a 24 hour slant. Agar plates containing 10 fold dilutions of G-11 were inoculated on the surface with a loopful of the same suspen-

sions each spread over an area of about 1 square centimeter. Readings were made after 48 hours at 37 degrees C.

Three strains tested in broth were completely inhibited at a dilution of 10^{-6} with partial inhibition at 10^{-7} . Twenty strains were tested on agar at a 10^{-6} dilution 2 strains showed only partial inhibition 3 showed almost complete inhibition and the remaining 15 failed completely to grow. At 10^{-7} all 20 strains grew as well as on the control plates. Three gram negative organisms (coliforms) tested in the same manner grew in concentrations of G-11 10 to 100 times greater. Parallel tests on zephiran chloride showed similar bacteriostatic levels, including the greater resistance of gram negative bacilli.

Bacteriostatic effect of wash waters obtained from individuals in contact with G-11. In view of this demonstration of marked bacteriostasis in low concentrations of G-11 the wash waters obtained from skin tests on persons in contact with G-11 were tested directly for their bacteriostatic effect when incorporated in agar plates in 0.1 and 1.0 milliliter amounts. Three persons who had been subjected to the standard G-11 surgical wash (see below) once daily for 5 days, followed by a 2 day lapse were again given the standard G-11 wash and re-

quired to wear dry sterile gloves for 42 minutes. They were then tested and 1 water added to agar plates in 0.1 and 1 milliliter amounts. Four of the strains in normal skin were tested by inoculation of the surface of these plates. The results given in Table I showing that with the medium described in the previous section, marked inhibition was present in the plates containing the 1.0 milliliter samples against all strains with partial inhibition in the 0.1 milliliter samples. Taking into account the 10 fold dilution of wash water in agar with the 10 ml liter sample from 1 to 10 milligrams of G may be carried over into the bath from the skin under these conditions. On a few occasions there has been evidence of slight inhibition from samples obtained 24 hours after the last G-11 application but this was less striking than that seen in samples taken 42 hours after contact. In no case was a G-11 serum used in the procedure for obtaining the counts.

In the attempt to neutralize this inhibitory effect in the medium infusion agar was tested since it had been employed by Traub with indication of bacteriostasis. It is evident in Table I that some neutralization has occurred since the 0.1 milliliter samples, with a few exceptions, showed no inhibition. However the 1.0 milliliter samples were still markedly inhibitory. The addition of 1 per cent of the serum in a concentration of 1 per cent to the tryptone-extract agar completely obliterated the bacteriostatic effect of the traces of G-11 carried over from the skin. Table I. In explanation of this effect it was found that the bacteriostatic potency of G-11 was depressed about 100 fold by the addition of 1 per cent serum to the agar or broth used for testing.

The method of testing for bacteriostasis given in which relatively large numbers of organisms are applied to a small agar surface is not as sensitive as are poured plate tests in which isolated organisms are exposed to the material. Therefore, poured plates containing known numbers of normal skin bacteria in the presence of measured amounts of wash water were prepared in order to approach more closely the conditions under which the skin counts are obtained. The results are given in

able II the inhibitory effect of 10 milliliter wash water (Specimen A in Table I) was again demonstrated in all media except those containing 1 per cent serum. The substitution of Witte peptone for tryptose resulted in a slight improvement. It is difficult to reconcile these findings with those of Traub who disclaims any such effect. He does not state the interval between the last application of G-11 and the collection of the sample in his studies; this interval would presumably be variable. It is possible that his infusion medium happened to contain more inhibitory substances than did ours. As a result of these observations all counts referred to hereafter were made in tryptose-extract agar containing 1 per cent serum unless otherwise specified.

Surgical wash with G-11. A liquid soap containing G-11 was used since a more uniform application is possible in contrast to a bar soap with which an undeterminable amount is applied to the skin. A 1 per cent preparation was finally adopted made as follows: 10 grams of the monopotassium or monosodium salt of G-11 were dissolved in 50 milliliters of hot 95 per cent ethyl alcohol. The alcoholic solution was added with thorough mixing to 1 liter of soap solution prepared by dissolving 200 grams of clear potash soap in 800 milliliters of hot distilled water. Both solutions were cooled before mixing. The final product contained 5 per cent alcohol and all control soaps were also made up in 5 per cent alcohol for comparison. The standard wash procedure was as follows:

1. The hands and arms were wet in tap water and a large palmful of G-11 soap solution applied to each hand and arm. Persons with small hands used 2 palmfuls. Over a period of 1 minute the soap was lathered into the hands and arms.

2. This was allowed to remain for 2 more minutes during which waiting period the nails were cleaned.

3. After a tap water rinse 1 and 2 were repeated with the omission of the nail cleaning. Thus the skin was in contact with the solution over a 6 minute period.

4. After another tap water rinse the hands and arms were immersed for approximately

Plates represented in each vertical row received the same number of organisms. As is evident in the last horizontal (control) row the numbers of organisms in the inoculum varied from one strain to another.

Wash water A from subject A (Table I) washed with G-11 45 minutes before sample was taken. Culture on 1 ml. of ash at alone + 1% serum gave 1 colony.

Wash water D from individual treated with control soap without G-11. Remainder of treatment as the same, including the alkaline rinse. These washings were autoclaved before use. Culture as sterile.

5 seconds each in an aqueous solution of zephiran chloride 1:1000 and dried on a sterile towel. The disinfectant rinse contributes nothing to the effect beyond destroying hypothetical organisms in the tap water left on the hands. If a fresh sterile water rinse is available for each individual the zephiran rinse may be omitted.

In testing the effectiveness of this procedure under various conditions the test subjects after washing powdered their hands with sterile talc and wore dry sterile gloves for 45 minutes before determining the skin population. Questions relating to practical operating room routine were investigated. Direct comparison with a conventional 10 minute surgical scrub with a brush followed by an alcoholic zephiran chloride 1:500 rinse was carried out. The effectiveness of the first G-11 application was tested. The not uncommon practice of changing gloves between operations with only a limited skin cleansing was also considered in relation to the use of G-11. The effect of its interrupted or nondaily use was examined and its effectiveness in alcohol rather than in soap solution was tested.

Five subjects 3 men and 2 women were tested through 3 consecutive mornings of

simulated operating room conditions. None had been in contact with G-11 previous to the experiment. The results appear in Table III. On the first day they scrubbed for 10 minutes with Ivory soap cleaning the nails during the scrub. They then rinsed in tap water and in a 1:500 zephiran chloride solution in 70 per cent alcohol. The hands were dried on a sterile towel, and dry sterile gloves worn for 45 minutes during which the usual laboratory work was performed. The skin organisms were then estimated the residual Ivory soap resulting from this determination rinsed off in tap water the alcoholic zephiran rinse repeated the hands dried on a sterile towel and gloves again worn for 45 minutes. This was repeated giving a total of three 45 minute periods in gloves. On the second day the standard G-11 wash was introduced, no brush was used. Again 3 glove changes at 45 minute intervals were made and the aqueous 1:1000 zephiran rinse was used throughout. This procedure was repeated on the third day. It will be noted that only two 6 minute applica-

tions of G-11 soap were made the material was not used at any other time.

Several points of practical interest are noted in Table III. The rise in the skin population following a surgical scrub with glove changes is apparent, and is in agreement with the findings of Price. Moreover the first application of G-11 without previous contact results in counts lower than those obtained with a surgical scrub. An individual could be introduced into a surgical group after only one 6 minute contact with G-11 although an additional contact on the preceding day would be preferable. The progressively increasing effectiveness of the agent is seen in Table III from the counts obtained on the second day of its use.

The data presented in Table III do not represent the maximum effect obtainable probably because the 3 skin counts performed on each person each day with the attendant prolonged Ivory soap lathering etc. G-11 from the skin. It has been found that alcohol rinses have the same effect and are to be avoided. To demonstrate a greater effect of the material which would obtain under normal conditions of use 5 other persons, 3 men and 2 women were given the standard G-11 wash daily for 4 days. No skin test was done nor was any other G-11 used. On the fifth day they changed gloves at 45 minute intervals as before but, instead of being tested between each change they washed their hands briefly (15 seconds) with G-11 soap, rinsed with tap water and with aqueous zephiran. The counts appearing in Table IV were obtained at the end of the third 45 minute period and were consistently low throughout. These superior results are attributable to the

maintenance of a higher level of the agent in the skin and show that a brief wash with G-11 between glove changes will prevent the rise in bacterial numbers which occurs with ordinary procedures.

Effect of interruption of daily G-11 application. Three persons after going through the standard G-11 wash for 5 days were not treated or 2 days. On the third day thereafter they again carried out a standard wash wore gloves or 45 minutes and were tested. The results appear in Table V and indicate that there is persistence of the effect over this interval. It seems unnecessary to subject the surgical team to daily contact with the agent in order to maintain the effect unless a lapse of more than 2 days takes place.

Effectiveness of G 11 in alcoholic solution. It was found that 33 per cent ethyl alcohol by volume was required to hold 1 per cent of the monopotassium salt of G-11 in solution at room temperature. The effectiveness of this 1 per cent G-11 in dilute alcohol in contrast to a solution of the material in 20 per cent soap was tested as follows: 5 subjects who had not been in contact with G-11 for over a month washed their hands briefly (about 15 seconds) in Ivory soap and cleaned their nails. They then rinsed in tap water and dried on a non-sterile clean towel. After immersing each hand for about 5 seconds in the alcoholic G-11 solution they allowed this to remain for 2 minutes after which they repeated the 5 second G-11 immersion again allowing it to remain on the hands for 2 minutes. This time interval was employed since the skin dried almost completely in 2 minutes after the first immersion. Following a tap water rinse the hands were immersed for about 5 seconds each in aqueous zephiran chloride 1:1000 and dried on a sterile towel. Gloves were worn for 45 minutes followed by the usual estimation of skin organ-

isms. The results obtained on the second day of this treatment including 3 control persons treated in the same manner except for the substitution of 33 per cent alcohol without G-11 are shown in Table VI. It may be seen that the alcoholic G 11 is as effective as a soap solution of the agent, however the possibility was pursued no further because of the marked preference of the subjects for the soap solution which proved to be considerably less irritating. It appears that more G-11 is released into the test basin in this procedure than was found in the studies on soap solutions. Five per cent serum was required to eliminate the bacteriostatic effect of these washings in contrast to the 1 per cent serum needed for the soap solution of G-11.

DISCUSSION

The compound G-11 incorporated in soap appears to be a valuable agent in the cleansing of skin. The available evidence suggests that it is taken up by skin and retained for considerable intervals exerting a constant bacteriostatic (if not bactericidal) effect on the resident flora. It is equally effective in dilute alcohol solution but this has been found to be more irritating than the soap preparations. Under certain conditions bacteriostatic amounts of G-11 are extracted from the skin and carried over into the medium in the process of enumerating the skin bacteria a fact which must be recognized as a source of error in evaluating effectiveness. With proper attention to details of concentration and length of exposure of the skin to this agent, the use of both the scrubbing brush and the somewhat irritating alco-

hol rinses may be eliminated from preparation of the surgeon's hands and arms. Its exclusive use whenever soap is employed is unnecessary for persons going through a single surgical wash as outlined above on each of 5 days a week. Lapses of longer than 2 days reduce the effectiveness of the material. No irritation or sensitivity has been encountered in our studies on G-11 with the exception of one scrub nurse who developed a measles-like eruption about 6 hours after her first application. This disappeared on subsequent applications. It would not be surprising if occasional instances of true sensitization were to appear.

Another obvious use of G-11 is in the preparation of the patient's skin in elective surgery in which a few days are available to attain the full effect. It should be pointed out that G-11 is not a substitute for more potent materials such as iodine which though limited to the superficial skin organisms exert a prompt action. For example the contamination of the skin by pus would have to be dealt with in the usual way. One might anticipate that G-11 would be ineffective in open wounds in view of the inhibitory effect of serum.

SUMMARY

The incorporation of G-11 (2,2-dihydroxy-3,5,6-trichloro-4-hexachloro-diphenyl methane) in

soap used for the preparation of the surgeon's skin reduces the numbers of skin organisms considerably below those found after conventional scrub procedures. Broadly speaking, bacterial counts of the washings of untreated hands range in the millions of organisms per liter. Conventional surgical scrubs followed by germicidal rinses reduce the number about tenfold and the G-11 wash accomplishes a reduction of about a thousandfold from normal skin counts. In addition the time consumed is shorter and the scrubbing brush and strong germicidal rinses are unnecessary.

Individuals receiving the 6 minute application described, once each day 5 days per week, would require no further daily contact with G-11 to maintain its effect. When changing gloves between operations, a brief wash with G-11 soap is sufficient to keep the skin counts at a low level. Prolonged lathering with plain soaps, and the use of alcohol rinses decrease the effect, presumably by extracting G-11 from the skin.

PLASMA FRACTIONS—"FIBRIN FOAM," THROMBIN, AND "FRACTION NO 1"—IN GENERAL SURGERY

JOHN FALLON M D F.A.C.S. and WILLIAM F CROSKERY M D
Worcester Massachusetts

An active preparation of beef thrombin was announced by Mellanby in 1933 and Seegers and McGinty later reported a preparation of greater activity. Parfentjev's monograph on the fractionation of rabbit plasma provided the basis for the study of the globulin-containing fraction with thrombic activity (18). Several clinical applications of animal thrombin were reported by Tidrick. Additional reports on its use in cases with prolonged bleeding time (hemophilia, symptomatic thrombocytopenic purpura, hypoproteinemias, and hereditary thrombasthenia) were made by Lozner and his associates. The antigenicity of thrombin was studied by Light (11) who also with others (12-16) reported the use of thrombin applied on special gelatine sponges instead of fibrin foam.

Cohn and his co-workers in fractionating pooled human plasma produced fraction No 1 thrombin and fibrin foam.

Foam is a sponge-like brittle solid which soaked in thrombin becomes gelatinous and applied topically produces rapid clotting. For more detail of the physical and chemical properties the reader is referred to the original reports (3, 7, 8).

Bailey and Ingraham (2, 9) studied the hemostatic properties of the foam thrombin combination. In the experimental animal bleeding from wounds in the liver, peritoneal cavity, kidney and lungs was controlled. It was shown that the presence of foam did not impair the efficiency of the sulfa drugs or penicillin. Use of the foam thrombin combination in man first was reported by Ingraham (10) and later by Woodhall both of whom

The products of plasma fractionation employed in this work were developed from blood which was collected by the American Red Cross, by the Department of Physical Chemistry, Harvard Medical School, Boston, Massachusetts, under a contract received by the Committee on Medical Research between the Office of Scientific Research and Development and Harvard University.

used it in neurosurgical operations. Anderson and Kentros reported a successful application at dental extraction in the case of a hemophilic patient.

Cohn's fraction No 1 derived from plasma, consists of light amorphous particles which are approximately 80 per cent fibrinogen. Cronkite and others are credited with the first application of fibrinogen and thrombin as an adhesive for skin grafts. Dees reported their use at pyelolithotomy to form a coagulum in the pelvis which would trap stones.

We have used plasma fractions obtained through the courtesy of Drs. Franc D. Ingraham and John T. Edsall, 250 times in 210 patients. The fractions used were thrombin, fibrin foam and fraction No 1. The purpose of the study was the development of applications for these substances in general surgery.

THROMBIN

Thrombin alone applied on a sponge, was used in 2 cases. The results were unsatisfactory.

FRACTION NO 1 AND THROMBIN

Fraction No 1 and thrombin were used in 12 cases to remove gravel from a renal pelvis in 1 case with only partial success as an adhesive for the skin flaps in 9 mastectomies as an adhesive under split thickness graft in 1 case around a split thickness skin graft in the making of an artificial vagina in 1 case. Results were good except in 3 cases in which more than the usual amount of serum accumulated lifting parts of the skin from the bed. In 1 of the latter cases infection developed with extensive loss of graft. The fluid accumulation may have been fortuitous, or it may have been from overproduction of secretion. We suspect, however, that it was from mechanical interference with drainage. Therefore we now are making it a practice to leave channels for

drainage and inserting small rubber tissue drains.

FOAM AND THROMBIN

Fibrin foam soaked in thrombin was used 236 times in 196 patients for one or more of three purposes first, as a hemostatic second as a filler of cavities and third as a dressing.

1 Use as a hemostatic While the bleeding is controlled by pressure, a block of foam, cut to size by razor blade or scalpel, was soaked in fresh saline solution of thrombin. The resultant jelly like mass then was held against the bleeding area by gentle pressure with a sponge or preferably the finger itself. Sometimes it was advisable to remove by suction excess thrombin which might interfere with adherence of foam.

Usually clotting was instantaneous. To some degree clotting time depends upon the strength of the thrombin solution. Occasionally one portion of the bleeding area continued to bleed. We interpreted this as meaning that the amount of thrombin in the first application was insufficient or that the application to the bleeding area was uneven. Invariably bleeding was controlled by a second or third application. We found that the release of pressure should be gentle to avoid disturbing the clot. Before foam was used it often was advisable to control the oozing by simple pressure until manipulations in the immediate neighborhood were finished. Sometimes it was advantageous to prepare in advance a flap of peritoneum or other tissue to suture over the foam pad. Interestingly this work with foam increased our respect for simple pressure as a hemostatic. Oozing areas ordinarily were controlled by pressure while foam was being prepared.

Sometimes bleeding which we would not have expected to control without suture had stopped by the time foam was ready. However when foam was used in addition we felt more secure against recurrence. Because of the possibility of generalized intravascular thrombosis, never under any circumstances should thrombin be injected intravenously. To prevent accidental aspiration into open veins on a bleeding surface one should apply pressure enough to close the veins from the instant when the pad is applied until clotting is complete.

The most commonly useful application was at thyroidectomy. Only the larger spurring vessels were clamped with 8 to 12 instead of 20 to 40 clamps per lobe. These clamps were tied. No second round of clamps was applied. The gland remnant was not sutured. Sheets of foam on the cut surface completed the hemostasis. The advantage is not just reduction of sutures and clamps. It is avoidance of trauma to the thyroid remnant. One may intend to leave a fifth or sixth of the gland. But if the sixth is full of compressing ties and sutures it may be physiologically a tenth. Also, the usual final suture of the gland remnant endangers the recurrent nerve behind the gland and necessity for this suture is eliminated by the use of foam.

Pancreaticectomy demonstrated another useful application. In 1 case a considerable amount of pancreatic parenchyma at the junction of body and head was resected. Both pancreatic ducts were cut. One was ligated the other anastomosed after resection of 3 centimeters. Foam was packed into the cavity and around the anastomosis. The cut surfaces were sutured together and the suture line covered by a foam dressing. The patient died on the 9th postoperative day from pancreatitis and bronchopneumonia. Postmortem examination showed leakage at the anastomosis but no bleeding. A cardiac patient whose pancreatic resection had necessitated anastomosis of the duct died from cardiac decompensation on the 5th postoperative day. Postmortem examination showed no infection or pancreatitis. The anastomosis was tight and there was no evidence of hemorrhage.

Foam not only has controlled bleeding from incisions into pancreas, liver and kidney but

blood pressure had returned to normal new applications of foam held. Two arteries of 4 millimeters could not be controlled by foam until the blood pressure had fallen to dangerous levels.

We do not propose the use of foam for openings in major vessels. In arteries there is the risk of delayed hemorrhage from a high head of pressure acting over a broad area. In veins there is the risk of indrawn thrombin. However, suddenly faced with an incision of the vena cava, one of our colleagues held a pad of foam on the opening by suturing peritoneum over it. The patient ultimately came to post mortem examination which showed neither hemorrhage at the site of operation nor distant thrombosis.

It is reiterated that foam is not recommended for the large vessel whether artery or vein.

Use as a filler of cavities. In 31 cases foam thrombin was used as a hemostatic filler which later was replaced spontaneously by reparative tissues. Usually only a small amount was needed. However, we have used up to approximately 25 cubic centimeters without bad

by replacing deep sutures it has avoided the bleeding which such sutures themselves cause and the danger to ducts which they involve. At every application in this group the foam was completely successful in hemostasis usually at the first application but sometimes only at the second or rarely the third.

Foam thrombin purposely was used 17 times in the skin or in the immediately subcutaneous tissues to allow naked eye observation of healing. The group included 10 applications at hemiorrhaphy. No gross difference was observed in those parts of the wounds where the foam was implanted.

Throughout this group of applications foam invariably succeeded in controlling bleeding. Foam thrombin was particularly beneficial when applied to tissues distorted by pathology which lay near vulnerable structures such as the hepatic duct, the ureter, the hypoglossal spinal accessory or phrenic nerves. Here foam substituted for blind clamping and deep suture. Commonest application in this group was to the subvesical veins at hysterectomy and in vaginal operations. The areolar tissue of the neck, erectile tissue of the labia, retroperitoneal spaces, mesentery and intestine proved practical sites for application. Several times foam was used for tamponading around the cystic artery stump which otherwise would have been left uncontrolled for fear of injuring hepatic ducts by clamping. Profuse bleeding from one severed aberrant cystic artery or major branch thereof was stopped immediately by foam. Following proctoscopic resection of a polypoid polyp from the base of a good sized sigmoid place by suture.

We did not use foam for control of direct hemorrhage from large vessels in the human. The largest artery that we tried to control and it was controlled immediately and satisfactorily was the rather small cystic artery resected in a patient with aortal blood pressure. However, in 8 operations upon dogs major arteries up to 4 millimeters in diameter were opened or transected. At normal blood pressure arteries of 2 millimeters and some of those of 3 millimeters were controlled by foam and digital pressure. Some clots blew off when hypertension was induced. After the

effect. In our experience the most satisfactory application of foam after thyroidectomy was in the removal of a Bartholin's cyst. Often in the past the small artery at the upper end of the cyst escaped our clamps retreated into the spongy perivaginal tissues, and bled. Wounds of operations for pilonidal sinus, wen and ganglion that is, cavities which could be watched from the surface healed well with foam fillings. In addition to the cases listed in Table III considerable amounts of foam were used in deeper cavities in other cases listed in Tables I and II (e.g. presacral neurectomy breast biopsy some of the gastrointestinal resections) with the secondary purpose of space-filling. None of these cases showed complications attributable to foam.

3 *Use as a dressing* Following an accidental observation that better epithelium seemed to grow more quickly under foam foam thrombin dressings were applied to 2 skin defects and 2 small mucosal defects (epulis, rectal polyp) and the results were satisfactory in each.

After preliminary trial in the dog foam also was used 5 times as an internal dressing wrapped around an intestinal anastomosis and as mentioned previously foam dressing has been used around pancreatic duct anastomosis. It was used once over an incision into the renal pelvis with inconclusive result. There seems to be some indication for its use in anastomosis but our experience has been too limited to be conclusive. In cases of femoral embolectomy foam worked well as an outer coat around the artery. However because of the normal risk of thrombosis in arteriorrhaphy our judgment in applying foam in these instances was questionable.

Foam proved an excellent dressing after anal operations. The anoscope could be reinserted after operation without fear of hemorrhage when it was followed by a foam thrombin plug in the anal canal. Foam from containers which had been opened for other operations was used for anal cases.

COMPLICATIONS

The absolute contraindication to the injection of thrombin intravenously and the danger of accidental aspiration into an opened vein

on a surface or in a cavity which we have tried to prevent by preliminary digital pressure, have been mentioned. Two of our 210 patients had femoral thrombosis. This incidence is high but the group is too small to form definite conclusions. It should be recorded also, that the group was picked from a larger series and contained most of those individuals of the total who were likely candidates for thrombosis. The increased accumulation of fluid under skin flaps or grafts when fraction No. 1 and thrombin were used was produced more by interference with drainage we believed, than by increased secretion. The consequent advisability of leaving drainage channels has been mentioned.

No other complications were met. Foam was used freely in conjunction with topical sulfathiazole or penicillin. Foam was used in infected cavities when they were near enough to the surface so that they could be watched, no complications were noted in these cases.

SUMMARY AND CONCLUSIONS

A few experiences with fraction No. 1 and thrombin are recorded. In 236 applications, foam thrombin proved an efficient hemostatic agent for incisions into solid organs and at sites such as soft surfaces or areolar spaces where ordinary methods of hemostasis are difficult of application or unsatisfactory in result. It may substitute for blind clamping and deep suture with their consequent danger to adjacent vulnerable structures such as a hepatic duct, ureter or nerve. It should not be used for large arteries or veins. Complications and dangers are discussed.

These blood fractions like their parent fraction plasma, are neither an excuse for sloppiness in technique nor a substitute for judgment. But, like plasma, they promise to extend a little the present boundaries of technical operability.

CLINICAL OBSERVATIONS ON FURACIN SOLUBLE DRESSING IN THE TREATMENT OF SURFACE INFECTIONS

E. R. SHIPLEY M.D. Baltimore, Maryland, and M. C. DODD Ph.D., Norwich, New York

FOLLOWING the report by Snyder Kiehn and Christopherson that 5 nitro-2 furaldehyde semicarbazone (furacin) 0.2 per cent in a water soluble base (furacin soluble dressing) was effective in the treatment of infected battle wounds, a study of this preparation on a series of infected surface lesions encountered in the patients in a civilian hospital was begun. The material presented here is the clinical and bacteriological results obtained during the local treatment of 90 cases of superficial infections.

FURACIN

Furacin is a yellow crystalline material having the structural formula $O_2N-\text{C}_4\text{H}_2-\text{CH}=\text{NNHCONH}_2$. It has been shown by Dodd and Stillman (2, 4) to be both bacteriostatic and bactericidal for a variety of gram-positive and gram-negative pathogenic bacteria, and Cramer and Dodd (1) have demonstrated that the activity is maintained in the presence of body fluids. In addition oral administration of the compound has been found (2) to produce a therapeutic effect on experimental infections in mice with both gram-positive and gram-negative bacterial species. Tests (3) in both rabbits and humans have shown the material to be nonirritating upon local application and no toxic symptoms have been observed in animals on which large amounts have been applied for long periods of time. Meleney and Johnson (7) have recently stated that this compound is active against gram-negative bacteria and satisfies the requirements for use in the local treatment of infection.

The compound is fairly insoluble in water (1:4100). However it was used as a 0.2 per cent solution in a mixture of carbowaxes

and propylene glycol in which it is soluble up to a concentration of 1.0 per cent. This base is water soluble, nonirritating and nontoxic, liquefies at body temperature and can be removed easily without scrubbing by washing with water. Many investigators (5, 8, 9) have reported on the safety of the ingredients. Recently Meleney and Johnson (7) have noted the advantages of this type of base for local use on the skin.

PROCEDURE AND METHOD OF EVALUATION

In all cases the preparation was applied to the area to be treated so as completely to cover the area. On superficial infections furacin soluble dressing was spread on gauze handkerchiefs, and laid over the wounds and held in place with gauze bandage. Deep wounds and cavities were filled with the ointment, and a dry dressing used to cover the area. Sinus tracts were irrigated with the melted ointment. Many patients were treated by covering the area with furacin soluble dressing without bandaging.

Cultures were taken by swabbing the worst appearing area of the wound following the removal of the ointment, every other day or at the time the dressings were changed if they were left in place for longer periods. Ninety-seven of the strains isolated were tested *in vitro* for susceptibility to the drug.

It was realized that the evaluation of a new agent of this type is a very difficult task. As a result an attempt was made to control as many of the extraneous factors as possible, such as bed rest, systemic therapy and surgical intervention.

Also the same criteria for evaluation were used wherever possible throughout the study and classification of results was done according to the method proposed by Meleney (6) for the evaluation of the effect of materials

From the University Hospital, Baltimore, Maryland.

following local application. He advises the division of results into four groups (a) brilliant, (b) good, (c) questionable and (d) with no effect. In order to prove any definite benefit from a material Meleney (6) believes that without controls the results must fall into the brilliant or good classes in most cases.

CLINICAL RESULTS

Following the classification given it was found that of the 90 cases reported 26 fall into the brilliant group 44 into the good group 13 into the questionable group and 7 into the group showing no effect. Thus, 77 per cent of the cases fall into the first two groups which fact would definitely qualify the treatment as valuable by this classification. It must be realized that many of the lesions treated consisted of a superficial infection superimposed on a previously existing skin lesion such as lupus vulgaris herpes zoster or erythema multiforme. No effect was noted on the original condition in these cases but the superficial infection responded well and rapidly to the application of furacin soluble dressing. The number and types of lesions treated and the results are summarized in Table I.

In the treatment of diabetic gangrene it has been realized that any local application including furacin soluble dressing has no effect on the infection and on the gangrenous process unless early adequate surgical intervention is carried out. Unless adequate drainage is instituted early furacin soluble dressing will not prevent a lymphatic or tendon sheath spread of the infection upward. In the 8 cases of diabetic gangrene reported 6 cases showed good results. In each of these 6 cases, early adequate surgery was instituted. In 2 cases surgery was not carried out, but it was found that where furacin dressing came in contact with the infected areas that were draining well, there was a marked improvement. There was a marked decrease in the odor from all 8 patients treated with furacin soluble dressing.

Two patients with compound fractures were treated with furacin soluble dressing. This ointment stops any spread of infection and prevents to a great extent the slough and the drainage seen following a large compound fracture.

TABLE I — LESIONS TREATED WITH FURACIN

Diagnosis	No. cases	Brilliant	Good results	Questionable	No effect
Diabetic gangrene	8		6		
Compound fracture	2	1	0		
Chronic osteomyelitis	3

Wounds	6	1	3	1	1
Ulcers	1		1		
Epidemiophytosis	3		1	2	
Acne vulgaris	6	3		0	
Total	40	0	3		
	90	26	44	13	7

Three patients with chronic hematogenous osteomyelitis have been treated by irrigation of sinuses with the melted ointment and by local application. The results here have been very disappointing. In 1 patient there was some reduction in the amount of drainage and some tendency to heal, but these results were entirely questionable.

Under the heading of loss of skin we have classified the patients who have been burned and patients who have had avulsion of large areas of skin. In each case there has been a marked reduction in the number of organisms present on culture. There has been a very marked reduction in the discharge from the wound and all wounds have healed and granulated well. In 6 cases in which skin grafting has been carried out either by the split thickness or punch technique the majority of the grafts have taken. In none of these cases was an attempt made to clean the recipient area of the furacin soluble dressing before the grafts were applied.

In 28 cases of infected lesions of the skin such as lupus vulgaris, erythema multiforme, chronic eczema and herpes zoster the results could be classified as brilliant in 14 and as good in 12. In every case the infection was superficial, and the ointment could reach the invading organism. Two cases of tuberculosis cutis and 1 of lymphogranuloma inguinale, showed only questionable results.

The treatment of deep-seated abscesses such as deep abscess of the buttock and abs-

cesses of the thighs following infusions, the ointment has been of no avail unless early adequate surgery and drainage have been carried out. If drainage is adequate and the abscess cavity is packed with furacin soluble dressing the walls appear healthy in 48 to 72 hours, and healing time is shortened by several days. At the same time, the odor and discharge from these wounds are markedly reduced.

Many infected wounds have been seen at this hospital either following an operative procedure or following trauma and it has been found that if these wounds are adequately drained surgically and the ointment is applied there will be a marked reduction in the number of invading organisms, a reduction in the amount of drainage and a great diminution in the odor from the infected area. One patient developed a fulminating wound infection in a right paramedian incision which followed an emergency small bowel resection. Twenty three days after the development of this wound infection but while the wound was still open the patient developed an obstruction. A left paramedian incision was made with no attempt being made to wall off the original infected wound. The second incision did not become infected, both wounds having been covered with furacin soluble dressing.

Fifteen ulcers of the leg due to vascular disturbances have been treated with furacin soluble dressing. In each case the superficial infection has been controlled very well and very rapidly. No change has been noted in the primary lesion except those changes that would be compatible with an improvement in the infection. These ulcers granulate well and there seems to be no retardation of epithelization. Several of these ulcers have been skin grafted over furacin soluble dressing with an excellent take of the grafts.

Six cases of acute athlete's foot have been treated with furacin soluble dressing. There is almost an immediate response of the secondary infection superimposed on the epidermophytosis, and the patients noticed much relief in 12 hours. In 3 cases the patients have noticed a rapid healing of the original epidermophytosis, and in 2 cases of chronic epidermophytosis not listed in Table I there

has been some improvement in the athlete's foot. This is probably due to the 25 per cent propylene glycol in the ointment base which is somewhat fungicidal.

Four cases of acne vulgaris of the face have been treated with furacin soluble dressing. It has been found that the number of comedones and the number of acute pustules has been diminished greatly by the use of furacin soluble dressing once a day at bedtime.

Several cases not listed in Table I have been treated with furacin soluble dressing in an attempt to prevent any expected infection. In 2 patients who had a Torek operation, the scrotal-thigh incision was covered with furacin soluble dressing in the operating room, and no slough or infection occurred. In 2 patients who had a Mikulicz colostomy through an inguinal incision the incision healed by early granulation even in the presence of fecal material.

In all cases, special attention was given to the effect of treatment on the base of the lesions and the effect on the discharge and odor. In these respects the following generalizations can be made:

The base of the lesions treated has shown no change in 14 of the 90 cases. In the majority of cases with secondary infection the infection disappears almost at once, leaving a clean base. Granulations in the base of ulcers appear early, appear healthy and red, but do not tend to overgrow the skin edges. There is no retardation of the epithelization of these wounds by use of the dressing.

The discharge from a wound is lessened in the majority of cases. 79 of our 90. The discharge decreases in amount within 24 to 48 hours after the original use of the ointment. This diminution prevents the maceration of the wound by a purulent discharge.

The odor of foul wounds is improved within 24 hours after the use of furacin soluble dressing. The reduction in the odor is closely allied with reduction in the number of invading organisms. Particularly is the reduction of odor noted in the treatment of foul draining stasis ulcers of the extremities.

Irritation. Comparison with other drugs. Fifteen of the patients treated with furacin soluble dressing had had local applications of

TABLE II.—CLINICAL SUSCEPTIBILITY OF STRAINS OF BACTERIA ISOLATED FROM LESIONS TO FURACIN SOLUBLE DRESSING MEASURED BY BACTERIOLOGICAL CULTURE RESULTS

sulfathiazole ointment 5 or 10 per cent for 1 to 2 weeks prior to their coming to us. In these patients the sulfathiazole ointment either showed no effect on the lesion or caused some type of local irritation. In all cases after discontinuance of the sulfathiazole ointment and the application of furacin soluble dressing there has been a marked improvement in the lesions.

Patch tests have been done on 30 patients by use of furacin soluble dressing sulfathiazole ointment 5 per cent and a tyrothricin ointment. In the 30 cases there has been no reaction to furacin soluble dressing. There have been 4 patients who have shown a red weeping macular to papular area under the lesion treated with sulfathiazole ointment. Nine patients of the 30 have shown a marked edema and bulla formation under the patch test for tyrothricin ointment. This high incidence of skin reaction to the ointment base used. In our usual experience the reactions to tyrothricin ointment are fewer in number. This lack of reaction of the tissues to furacin soluble dressing is borne out well in the treatment of the 90 patients. In this series only 2 patients developed any dermatitis at all. One patient developed a fine red papular

rash under the area treated after 44 days application of furacin soluble dressing. The other patient developed a similar rash after 8 days' application of furacin soluble dressing. In both cases the rash disappeared within 48 hours after discontinuance of the ointment. In this respect furacin soluble dressing appears to be superior to other ointments so far presented for local application.

BACTERIOLOGY

Culture findings. The lesions of the patients treated with furacin soluble dressing in this study were carefully cultured before and during treatment. Swabs from the lesions pus or body fluid were cultured aerobically and anaerobically on appropriate media. These samples were plated in a uniform manner so that rough estimations of the numbers of colonies produced could be made and by this method reduction as well as disappearance of the wound flora could be determined within the limits of error of the method. As shown in Table II column 1 172 strains comprising 13 species of organisms were isolated. The gram positive cocci and diphtheroids predominated appearing as 71 per cent of the total cultures. Among these were *Staphylococcus aureus* *Staphylococcus albus*

hemolytic streptococci and diphtheroids. The last named were not classified further as to species but grouped under the one general heading. Of the gram-negative flora encountered *Proteus vulgaris*, *Pseudomonas pyocyanea* and *Aerobacter aerogenes* were most frequent. Surprisingly only 3 strains of *Escherichia coli* were isolated. Except for this infrequent occurrence of *Escherichia coli* these findings are in good agreement with all reports on the pathogenic flora of civilian wounds and lesions.

Clinical susceptibility as measured by culture reduction. In Table II are also given the actual numbers and the percentage of the cultures isolated which showed a reduction in the number of colonies produced from the clinical material. This is shown in column 2. Column 3 shows the numbers and percentages of cultures which were completely negative and column 4 the number of cultures showing no change during the period of time which the cultures were followed. The last column presents the number of cultures which were not followed beyond the original isolation and identification either because the patient did not return or subsequent examinations showed the lesion healed.

The criticisms inherent in the procedure used in determining merely the reduction of the flora of lesions is clearly recognized. I.e. the type of lesion, the method of obtaining the samples, the presence of drug carried over in the sample and the plating technique. However the data are presented in light of this criticism as an effort to present as careful and controlled a study as was possible under the conditions. Thus the findings in column 2 showing that 87 or 81 per cent of 107 cultures (total cultures minus those on which no data were available) are subject to the above criticisms as to their value in showing the effect of the drug treatment.

It is generally accepted however that negative cultures are of value in estimating the effect of treatment on the infecting agent. In this study column 3 shows that of the 107 strains followed 68 or 63 per cent became negative during treatment with furacin soluble dressing. An examination of the data showed that this action was accomplished in some

cultures in as little as 24 hours while others required as long as 30 days for reversal. For their correlation of these figures with the clinical improvement in the lesions is not possible because of the presence of several organisms in any one patient, all having variable susceptibility. Thus, in some cases, healing of the lesion progressed rapidly with the disappearance of one species originally present, although another might remain without any noticeable effect even after completion of treatment.

In column 4 are given the numbers and percentages of strains which showed no change in the quantity of colonies produced by succeeding clinical samples during the course of treatment and thus labeled resistant or nonsusceptible to furacin. It is only fair to point out, however that in some cases, the period of time on which such a conclusion is based is relatively short and may not represent a fair test of the drug. For example, many strains were exposed to the drug for only 3 to 4 days, at which time the lesions were improved clinically or had healed sufficiently to stop treatment, yet the organism remained. In addition many of these cultures were found to be susceptible to furacin when tested *in vitro*.

As a group the gram-negative species showed a larger number of nonsusceptible strains than the gram-positive group with the exception of the diphtheroids. *Proteus* (40%), *Bacillus pyocyaneus* (37.5%), *Escherichia coli* (33.3%) and *Aerobacter aerogenes* (25%) were resistant in the order given. In the gram-positive group only the diphtheroids showed a similar resistance. The pyogenic cocci on the other hand, were on the whole most susceptible. Resistance in this group was as follows: Diphtheroids (37.5%), *Staphylococcus albus* (12.5%), *Staphylococcus hemolyticus* (7.1%), *Staphylococcus aureus* (6.6%), *Staphylococcus anhemolyticus* (0).

It is quite possible that the high percentage of resistance in the diphtheroid group may be due to lack of sufficient exposure to the drug because of a limited treatment period, and perhaps to the existence in this group of a particular species which is more resistant than others.

Susceptibility in vitro Ninety-seven strains of the cultures isolated in this study were examined *in vitro* for their susceptibility to furacin soluble dressing furacin (1-500) in carbowax and water and to the base alone (carbowaxes 1500 and 4000 and propylene glycol). In this way, the relative merits of furacin and the base ingredients as antibacterial agents could be evaluated.

The tests were done by a modification of the standard F D A. cup plate test the medium employed being the only variation from the standard procedure. Brain heart infusion agar (difco) was substituted because of its ability to produce better growth of streptococci and diphtheroids. All zones of inhibition measuring 1 or more millimeter were considered proof of antibacterial action.

The results are listed in Table III. It is pertinent to point out that the base itself minus furacin showed an antibacterial effect on only 4 strains out of 97 while furacin soluble dressing affected 93 of the total and furacin itself 89. The discrepancy in the latter two figures is due to a finding of 1 or more millimeter for furacin soluble dressing and zero for furacin with several strains.

Only two groups *Pseudomonas pyocyanea* and *Staphylococcus albus* showed strains resistant to furacin soluble dressing *in vitro* susceptibility being 83 and 89.4 per cent, respectively. With furacin in carbowax and water these two groups were 58.3 and 84.2 per cent susceptible respectively. *Pseudomonas fluorescens* group were 100 per cent susceptible to furacin soluble dressing but only 87.5 per cent susceptible to furacin. All other groups were 100 per cent susceptible.

The results obtained on the clinical and *in vitro* susceptibility of *Pseudomonas pyocyanea* are surprising in view of the previous reported facts (2, 4) that this organism is resistant *in vitro* to the maximum aqueous concentration of furacin possible (1-5000). Also Snyder Kiehn and Christopherson reported that this organism was not susceptible clinically or *in vitro*.

Several factors may explain these apparent discrepancies. Clinically *pyocyaneus* usually appeared in combination with one or more organisms. In many cases these latter were

TABLE III.—STRAIN SUSCEPTIBILITY IN VITRO TO FURACIN SOLUBLE DRESSING FURACIN AND BASE

susceptible and as they disappeared an apparent symbiosis with *pyocyaneus* was destroyed so that it perhaps disappeared because of the natural body processes and only secondarily as the result of the drug.

The *in vitro* susceptibility may be the result of the ten fold increase in concentration available in furacin soluble dressing over the tests run in aqueous solution. Also it was noted that the majority of zones of inhibition produced in the tests on *Pseudomonas pyocyanea* were about 1 or more millimeter in size the minimum required for a rating of susceptibility whereas all zones on *staphylococci* for example measured from 5 to 10 millimeters. It is therefore probable that the variation occurring in strain resistance in this species causes the appearance of some strains susceptible to 0.2 per cent of the drug. However *Pseudomonas pyocyanea* probably should not be listed as susceptible until more data are available.

CONCLUSION

The usefulness of furacin soluble dressing in the treatment of superficial infection has been fairly well established. It is known that the drug must reach the invading organism to cause any bacteriostatic or bactericidal effect.

Furacin soluble dressing does not remove the need for adequate surgery. The outstanding property of this ointment is the immediate reduction of the odor and drainage from a wound. There has been no evidence that the ointment retards or prevents epithelization or granulation of a wound. In fact the wounds appear healthy almost at once. The incidence of local skin reactions has been very low (2 in 90). The improvement in the appearance of a lesion has followed closely the decrease in the number of organisms plated out on culture.

It has been interesting to observe that the clinical improvement has paralleled the disappearance of one or more of the infecting organisms from the wound. The lesions have healed well when the symbiosis of the organisms has been broken up. The gram positive and gram negative species usually seen in surface infections showed a high degree of susceptibility to furacin clinically and *in vitro*.

SUMMARY

1. Ninety patients with local infections have been treated with a new ointment—furacin soluble dressing.

2. The ointment has been found useful in the treatment of superficial infections.

3. There has been a very low incidence of skin reactions to the drug (2 in 90).

4. The ointment must reach the organisms to obtain a bacteriostatic effect.

5. Clinically granulation tissue is not retarded in its growth.

6. Epithelization of the wound is not inhibited clinically.

7. The ointment will decrease rapidly the odor and drainage from a wound.

8. Furacin soluble dressing has shown less skin irritation or reaction than has sulfathiazole ointment or tyrothricin ointment to patch testing.

9. Culture results show a high degree of susceptibility to the drug of the gram-positive and the gram-negative flora which was encountered.

PROGRESS IN THE SURGICAL TREATMENT OF CARCINOMA OF THE ESOPHAGUS

THERE is an interesting parallelism in the evolution of the surgical treatment of carcinoma occurring in various organs of the body. After centuries of hopeless inaccessibility each important anatomical region has at last been brought within the reach of the surgeon's art. At first the attempts to extirpate the dread disease in each organ have met with failure and disappointment because of the imperfection of technical methods and the fact that the problem has usually been given over to the surgeon at first with reluctance and suspicion. Establishment of the correct diagnosis has often been delayed and an attitude of hopelessness has been assumed by the physician.

Various attempts to extirpate a cancer-bearing segment of the esophagus were made in the early years of this century. Notable among these was the work of Torek who per-

formed the first successful esophagectomy in 1912. But although the concept of the procedure was clear its performance was hampered by a lag in the technical developments needed to make the procedure sufficiently safe to justify its use routinely in the treatment of the disease. The passage of years was required for the realization of this goal as a result of improvements in the administration of the anesthetic, the conduct of the operation and the general preparation and subsequent care of the patient. It has therefore fallen to a new generation of surgeons to accomplish what was foreseen by the pioneers.

Although a few satisfying results have followed the use of the Torek operation the time has come to abandon this procedure because it is notoriously inadequate as a method of palliation and inefficient as a method of cure. During the last few years it has become possible to perform an operation which more nearly approaches the ideal of removing the esophagus and enough of the regional lymph nodes to afford a reasonable prospect of effecting a cure and which at the same time provides excellent palliation by restoring the continuity of the alimentary canal. This procedure consists of a radical excision of a large segment of the esophagus often including a portion of the cardiac end of the stomach, and of the majority of the regional lymph nodes to which metastases first go. It is completed by performing an esophagogastric anastomosis within the thorax. If the growth happens to be a high one, the anastomosis can be made in the very apex of the chest.

The advantages of this operation are obvious. It has been used in a sufficiently large number of cases to know that the operative

mortality is low enough to make the procedure practicable and to prove without question that it provides the most acceptable degree of palliation. This is particularly clear because it is most unusual for a recurrence of the disease to develop at the anastomotic stoma, so that the patient continues to swallow without obstruction as long as he may live.

From the standpoint of end results, the procedure is yet too new to allow accurate conclusions. There are only a few patients who have been operated upon more than five years, and relatively few more than three years. An encouraging beginning has been made, however and when we consider the progress which has already been made in the treatment of carcinoma of other organs, the future prospects of patients with carcinoma of the esophagus are indeed hopeful.

RICHARD H. SWEET

FRACTURES OF THE OS CALCIS

FEW fractures present so many and such difficult problems in their management as do fractures of the os calcis. The great variation in the severity of the injury the frequent involvement of the subtalar joint and the technicalities involved in the reduction of the fracture combine to make this a major treatment problem in the field of fracture surgery.

Experience with fractures of the os calcis has been enormously broadened by the recent war. Land mines (both antitank and anti-personnel, but especially the former) and ship sinkings by mines and torpedoes, made fracture of the os calcis a frequent injury with features so distinctive as to create almost a new kind of fracture characteristic of this war. Such war fractures caused when the floors of

vehicles and the decks of ships were driven up with great force against the heel, were of great severity the os calcis shattered into many fragments which were grossly displaced. The injury was explosive in its effect upon the bone, and the fracture often was compound. Effective early treatment was handicapped by the exigencies of forward-area surgery by the problems of an open wound, by circulatory embarrassment from swelling and trauma, and by transportation problems which made it impossible to segregate them for special treatment. Many came to amputation. Feet which escaped amputation presented major problems in reconstructive surgery with little hope of restoration of the tarsus to normal shape and function. So severe were war fractures of the os calcis that they constitute a group almost by themselves, related only distantly to the fractures of the os calcis of civil life.

No fracture illustrates better than does fracture of the os calcis the truth of the axiom that, in fractures, early treatment determines irrevocably the result in terms of structure and function. There is a brief and early period in which the maximum can be accomplished by treatment. If this moment of opportunity is allowed to pass by adopting a policy of wait and see, what can be accomplished by later treatment will never be as satisfactory. In fractures of the os calcis this period is short, for the cancellous fragments of the bone quickly cement themselves together into a mass which resists molding.

For the occasional surgeon the initial injury may seem a deceptively simple problem. The external appearance of the foot is changed little more than can be accounted for by the soft tissue swelling and the roentgenograms may be imperfect or difficult to interpret. The loss of function which will result from the injury is learned only by painful experience.

This is a fracture problem in which the services of an experienced and expert fracture surgeon are needed, and these should be sought in the early stage of treatment.

Imperfect or poor results after fractures of the os calcis are frequent and the degree of functional disablement is greater than might be expected from the magnitude of the fracture. A stiff, painful foot is the common end result and is caused by involvement of the subtalar joint by the fracture. As is the case with other intra articular fractures, joint function is certain to be impaired and painful if the fractured articular surface is not meticulously restored to normal position. Even the attainment of such perfect reduction of the fracture does not provide perfect assurance of good joint function. Other factors may combine to limit the most important, but at the same time the least recognized is avascular necrosis of a bone fragment carrying articular cartilage which is isolated from its surrounding contact by fracture fissures. When this occurs in such a manner as to deprive the fragment of blood supply even the most perfect restoration of position will not ensure perfect joint function. During the period of avascular necrosis the articular cartilage dies in whole or in part and is never perfectly restored. There is a rough patch on the articulation which ages the joint with every movement.

Difficulties of treatment and imperfection of results have led certain surgeons deliberately to advocate that no active treatment be undertaken for fractures of the os calcis, merely fixation in plaster in the position of the injury. Union has occurred. It is argued that treatment is simple and can be carried out in one and that the results are no more different than those obtained from more elaborate methods of treatment.

Such a policy of studied neglect is a confession of defeat. There is little to support its advocacy save its simplicity. Os calcis fractures like all other fractures will yield the best results when the fracture fragments are most perfectly reduced. This is especially true in intra articular fractures. Though this may be difficult to attain in fractures of the os calcis it is an ideal to be aimed at. The realization that it is difficult is the first step to devising effective measures of treatment. Boehler emphasized the value of traction to secure accurate reduction of the fragments. The use of traction can be broadened far beyond Boehler's concept with advantage. All other mechanical aids should also be used.

Because of the frequent involvement of the subtalar joint, it should be recognized that stiffness and painful function of this joint may result even when good reduction has been secured. Arthrodesis is a valuable form of treatment for this and should be utilized more frequently than it now is. Nearly every patient whose fracture shows serious fragmentation of the articular surface of the posterior facet of the calcaneus would be the better for arthrodesis. The suitable cases should be selected and the patients operated upon at an early date.

It is probable that for the extremely severe fractures with great comminution and great separation of the fragments as in war fractures, the removal of the whole bone as advocated by Pridie may prove to be a simple and reasonably satisfactory solution of a difficult problem.

The frequent occurrence of fractures of the os calcis in industry, the complexity of the problems involved in treatment and the importance of the end result make them a challenge to stimulate improved measures of therapy.

THE BOOK SHELF

THE INTERDEPENDENCE OF ARTIST AND ANATOMIST

VERA MOREL, New Orleans, Louisiana

FORTUNATE is the medical illustrator whose workshop adjoins a medical library. Within the restful quiet of book-filled walls, the eye and the mind may derive abundant and profitable pleasure from the study of plates that enrich and elucidate many of the treasured classical works. Present-day students and artists should be encouraged to take time out for browsing among historic volumes, thereby discovering and knowing intimately the illustrations of the early masters to whom we are so deeply indebted.

Contemplation of great works provides first surprises and interest, and as they become familiar there arises a desire to shift our attention to the individuals who created them. To learn something of their personalities, their surroundings, their problems—what they thought and felt and mainly how they worked together—this becomes a fascinating pursuit.

Collaboration and interdependence always have been essential to the peculiar requirements of medical illustration. The production of a medical book demands the concerted efforts of many minds and many hands, a co-ordination of crafts that are diverse yet closely interrelated. The artist is dependent upon guidance and in turn exchanges an ability to transfer his observations with accuracy, clearness, and technical proficiency. Possibly with the exception of the extraordinary genius Leonardo da Vinci, few artists have become scientists in the true sense of the word and while there have been medical men who were creditable illustrators only rarely did they attain greatness as artists.

How did the artist and the scientist work together? what was the attitude of one toward the other? was there friction and clash or harmony and possibly deep friendship? Expressions of warm admiration and gratitude for the contributions made by illustrators and engravers have

been recorded in the writings and biographies of medical men. In contrast, others have been silent, even secretive, and unsigned illustrations in some important anatomical works have brought about spirited controversies, speculation, and an absence of literature. Artists seem to have been strangely inarticulate about themselves.

Although there exists no published work of the brilliant young Veronese patrician, Marc Antonio della Torre (1478-1512?) and no book of illustrated anatomy was ever completed by his friend and countryman, Leonardo da Vinci (1452-1519), it is known that the two scholars were associated for a brief period of time. The influence of one upon the other is a matter of conjecture. Leonardo's passion for the study of anatomy long antedated his meeting in the year 1506 with della Torre who had come to establish a chair of anatomy at the University of Pavia. Giorgio Vasari (1511-1571), art historian of Italy, records that della Torre was one of the first to throw true light upon anatomy which up to that time had been plunged in the almost total darkness of ignorance. In this he was wonderfully aided by the talent and labour of Leonardo, who made a book drawn with red crayon annotated with the pen (of the subjects which he dissected with his own hand and drew with the greatest diligence). Vasari had visited Milan in the year 1566 and met Francesco Melzi to whom Leonardo had bequeathed his fugitive manuscripts and precious drawings which were destined to be scattered, hidden, and forgotten for two centuries.

One of Leonardo's later biographers, Edward McCurdy writes, "Leonardo was della Torre's senior by almost thirty years and Melzi supposed that he occupied the position of master with a pupil in these researches; others have supposed the position reversed. It seems natural that in the case of the two rare intellects working in unison toward a common purpose there would be neither master or pupil in the ordinary sense of the terms."

Mrs. Morel is medical illustrator at Tulane University of Louisiana, School of Medicine.

While Leonardo's notebooks record his thoughts and observations, little of his personal life is revealed therein and no mention made of della Torre who died aged 31 in the little epidemic-stricken town of Riva di Trento in the year 1512. The sudden death of the popular young master of anatomy may have caused Leonardo to abandon the plan he entertained for a comprehensive work of one hundred and twenty books on anatomy as he had written that "In this winter (1510) I believe I can send off this whole anatomy."

Any attempt to evaluate Leonardo's contributions to anatomy is beyond the intent of this study and difficult would it be to measure his certain influence upon modern medical illustration. Many of us have been inspired by the zeal and intense devotion he gave to anatomical science as well as by the intellectual force and unparalleled beauty of his impromptu anatomical drawings.

Whatever he draws, writes Rachel Annand Taylor, the effect of magical disquiet is Leonardo's enduring gift—a stir and expectation in the mind, a pulse and apprehension in the blood.

Would that we knew more of the relationship between the compassionate physician della Torre and the usually aloof Leonardo who has been styled the true founder of iconographic and physiologic anatomy. Both investigators embodied the exploratory spirit of the Italian Renaissance, that period of brilliant learning in art, literature, and science when observation assumed its rights and anatomy became articulate through pictures.

Meager and confusing are the facts concerning the artist or artists who worked with Andreas Vesalius (1514-1564) in the creation of his impressive and revolutionary publications. Many historians have been attracted by the romantic and enigmatical character of the young anatomist from Brussels who at the age of twenty-eight attained the summit of scientific greatness. In *De Humani corporis fabrica Libri septem* (1543) the structure of the human body was properly portrayed for the first time. Traditional methods of teaching anatomical science were supplanted by independent investigation and drawings after nature. As to the real hero of the *Fabrica*, opinions vary. Vesalius has been credited with the magnificent drawings as well as with their accompanying descriptive text. However in more recent years cudgels have been taken up in defense of Jan Stephan van Calcar (1499-1547) who had come down from Flanders to work under the great painter Titian in Venice where he acquired a mastery of the then new tridimensional effect achieved by the use of but two dimensions. For many years the beautiful woodcuts of the *Fabrica*

were thought to be the work of Titian, so able a follower of the master was Calcar. Christoforo Conolano also was credited with the unsigned drawings, and it has been suggested that the influence of Leonardo is reflected in these illustrations, but there is no support for this supposition. Nor is it wise to quote from Vasari's second edition of his *Lives of the Painters* (1568) wherein Calcar is mentioned for as the historian Charles Singer points out, Vasari's account does not aid in establishing the reality or the degree of Calcar's participation in the *Fabrica*.

Recently a handbook of Vesaliana has been provided in *The Bio-Bibliography of Andreas Vesalius* (1943) by the late surgeon and bibliophile, Harvey Cushing, who devoted forty years to the collection and study of all data pertaining to Vesalius. Cushing says of the *Fabrica* that as a book it has probably been more admired and less read than any publication of equal significance in the history of science. He gives the following lines of evidence to establish Calcar's association with Vesalius: (1) the allusion to Stephen in the introduction in the *Tabulae Sex*; (2) the occurrence of his name in the colophon of the last plate of the same work; and (3) the signed figure of the young artist in the engraved frontispiece of the *Fabrica*, evidently a self-portrait with the figure book in hand overseeing the dissection. There is

Whatever he draws writes Rachel Annand Taylor the effect of magical disquiet is Leonardo's enduring gift—a stir and expectation in the mind, a pulse and apprehension in the blood.

Would that we knew more of the relationship between the compassionate physician della Torre and the usually aloof Leonardo who has been styled the true founder of iconographic and physiologic anatomy. Both investigators embodied the exploratory spirit of the Italian Renaissance that period of brilliant learning in art, literature and science when observation assumed its rights and anatomy became articulate through pictures.

Weager and confusing are the facts concerning the artist or artists who worked with Andreas Vesalius (1514-1564) in the creation of his impressive and revolutionary publications. Many historians have been attracted by the romantic and enigmatic character of the young anatomist from Brussels who at the age of twenty-eight attained the summit of scientific greatness. In *De humani corporis fabrica Libri septem* (1543) the structure of the human body was properly portrayed for the first time. Traditional methods of teaching anatomical science were supplanted by independent investigation and drawings after nature. As to the real hero of the *Fabrica*, opinions vary. Vesalius has been credited with the magnificent drawings as well as with their accompanying descriptive text. However in more recent years credence has been taken up in defense of Jan Stephan van Calcar (1499-1547) who had come down from Flanders to work under the great painter Titian in Venice where he acquired mastery of the then new tridimensional effect achieved by the use of but two dimensions. For many years the beautiful woodcuts of the *Fabrica*

were thought to be the work of Titian, so able a follower of the master was Calcar. Christoforo Conolano also was credited with the unsigned drawings and it has been suggested that the influence of Leonardo is reflected in these illustrations but there is no support for this supposition. Nor is it wise to quote from Vasari's second edition of his *Lives of the Painters* (1568) wherein Calcar is mentioned for as the historian Charles Singer points out, Vasari's account does not aid in establishing the reality or the degree of Calcar's participation in the *Fabrica*.

Recently a handbook of Vesaliana has been provided in *The Bio-Bibliography of Andreas Vesalius* (1943) by the late surgeon and bibliophile Harve Cushing who devoted forty years to the collection and study of all data pertaining to Vesalius. Cushing says of the *Fabrica* that as a book it has probably been more admired and less read than any publication of equal significance in the history of science. He gives the following lines of evidence to establish Calcar's association with Vesalius: (1) the allusion to Stephen in the Introduction to the *Tabulae Sex*; (2) the occurrence of his name in the colophon of the last plate of the same work; and (3) the signed figure of the young artist in the engraved frontispiece of the *Fabrica*, evidently a self-portrait with the figure book in hand overseeing the dissection. There is

a signed *croquis* of the *Fabrica* title page bearing the name of Calcar. This fourth line of evidence is possibly more presumptive, but taken in association with the first three, it serves further to confirm their close relationship.

In the *Venesection Epistola* (1539) Vesalius writes his patron the physician Nicolaus Florenas of Brussels: "We have tried to make out a scheme of the dissections of this present year in the most convenient manner possible, but in view of the great crowd of spectators it proved altogether impossible to complete it and concludes: 'So if I have a number of suitable cadavers, and Joannes Stephanus (Calcar) the most admirable artist of our time does not refuse his assistance I shall not run away from my task. At another time Vesalius refers to Calcar's ability but the artist's name is omitted from the illustrations of the *Fabrica*. Whether this omission was for reason of ill-feeling, envy or mere inadvertence remains a perplexing puzzle.

Undoubtedly the impetuous Vesalius was a driving master and became impatient and grieved over any delay on the part of his coworkers. Calcar and other assistants may have preferred the pleasantness of ivory towers to the turmoil of the dissection scene where the dynamic young anat-

omist held the spectacular anatomical demonstrations at Padua which are so graphically portrayed in the frontispiece of the *Fabrica*. Vesalius refers to his own ability as a draftsman and three drawings of the six anatomical tables (1538) are by his hand, but the plates of the *Fabrica* are unmistakably the work of a trained and skilled artist who transcribed with fidelity and beauty what he observed and comprehended.

Despite personal difficulties that may have existed and the great amount of labor involved in the preparation of a comprehensive systematic anatomy in the space of a few years, the work reached completion and immortality. While no written account is available of the manner in which Vesalius and Calcar worked together, the *Fabrica* remains a perpetual source of inspiration and of joy and may be accepted as a glorious and certain instance of artist-anatomist teamwork and interdependence, although uncertainty as to the identity of the artist may still exist.

No name is signed to the copperplates in the early works of Guilio Casserio (Casserio) (1559-1616) but the following passage from the writings of Casserius is cited by Choulant: "I observed the muscle in the year 1593 on the seventh of March and immediately had it drawn for everlasting memory by that distinguished man Joseph Maumt, the German artist, who was at that time living in my household for the purpose of painting anatomic illustration. Casserius died before his ambitious anatomical projects were completed. In later editions of his works the drawings bore the name of Odoardo Flaletti and Choulant adds that owing to the correctness of Casserius' plates and their tasteful arrangement and the beauty of their technical execution, they mark a new era in anatomic representation and have become models for anatomic illustrations in copper.

Refreshing and illuminating are the accounts of Bernard Siegfried Albinus (1697-1770) whose investigations established an entirely new approach to illustrative anatomy. Albinus, professor of anatomy at Leyden from the age of twenty-one until his death, was an able draftsman and had keen appreciation of artistic ability in others. He secured the services of the most skilled artists and expended huge sums of money for the illustrations in his many works. We are told that he was assisted by the talented Jan Wandelaar (1690-1759) of Amsterdam, who had previously worked for Frederick Ruysche and Arent Cant.

Albinus describes in detail his methods of illustration and tells of the extra and occasionally burdensome effort required to train artists, stressing the fact that his illustrator reproduced nothing

that was not first thoroughly understood. He gives accounts of the various ingenious contraptions devised by himself for drawing of skeletons and musclemen in exact proportions. Of Wandelaar he writes: And so he had to be trained and guided and practically directed by me as if I were myself making the pictures, using him as a tool. Upon another occasion he remarks: I have often wondered at his spirit, his patience and resolution: he is moreover ardent and never without a certain impetuous eagerness of effort.'

Again he writes: 'He (Wandelaar) has reproduced everything with truth and accuracy and with a marvelous refinement of skill. He has reproduced all the smallest details and what is more difficult, the very appearance in so far as that art could. Still better is the fact that he draws beautifully and, what is even more important, draws the pictures on copper after the objects themselves. The great amount of attention that Albinus gave to the production of his illustrations was well repaid in the unparalleled results that he attained. Every word, and there are many that he has written is worthy of study and remembrance for he brings in strong relief the necessity for close co-operation between author and illustrator.'

We have a fondness for the extraordinary personality of Samuel Thomas von Soemmerring (1755-1830) who was a devoted follower of the great teacher Albinus. From the days of his boyhood Soemmerring was skillful with his pen both in drawing and in writing. His accounts of interesting travels, of friendships formed with noted medical men in other countries, and of personal struggles, make stimulating reading. Theodore Best writes: That his careful transfer of his observations and experiences into writing and sketches no doubt was a fundamental factor in his keen observation, accurate descriptions and clear illustrations later.

Soemmerring was fortunate to find Christian Koeck, a young artist, employed as a stucco-worker and model maker in an art shop near the University of Mainz who developed into an outstanding medical illustrator. He turned out admirable illustrations, unexcelled in purity, certainty and truthfulness, writes Choulant. But Koeck caused him a great deal of trouble especially when he went to Moscow where he was very unfortunate and could only return to Munich in 1809 after great pecuniary sacrifices on Soemmerring's part. In Frankfurt as in other cities Koeck lived with Soemmerring. He died in 1818.

Here also is an anatomist and an artist who left

us record of personal experiences in the preparation of graphic representations. Among Koeck's most beautiful drawings are those in Soemmerring's treatise on the eye. In the preface of this book, the author wrote: therefore I begged the artist to try his best to combine the greatest accuracy of individual details with the strongest retention of the whole, so that the finished product would produce the proper impression both from near and distant view. Truly accurate sketching costs no more effort than incorrect! Does it not, for example, cost the same effort whether I picture the hair of the eyebrow slanting as they lie in nature or horizontal as one finds them pictured so often?

The story of how Soemmerring created a female counterpart to the perfect representation of Albinus' male skeleton is a familiar one and it is interesting to surmise the extent of the mutual assistance required and the dependence of artist and author in this particularly difficult task. After many comparative studies the completed drawing was, as Choulant says, necessarily an idealized one since it had to represent not an individual form but the most beautiful form as it was imagined to exist in life. We quote the same authority, who explains the strong and lasting influence of

Soemmerring's illustrations in these words "They displaced all the repulsive, unaesthetic, and unnatural features so often prominent in earlier anatomic representations by the substitution of incomparably better ones."

Another great anatomist William Hunter (1718-1783) contributed great care and great sums of money in the production of his works. His volume of the *Anatomia uteri humani gravida* (1774) from the press of Joannes Baskerville, represents the work of many artists and many engravers. In the preface of this beautiful volume illustrated by talented men, including the famous Riemsdijk, are the following words written by John Hunter the famous brother of the author "He owes much likewise to the ingenious artists who made the drawings and engravings and particularly to Mr Strange not only for having by his hand secured a sort of immortality to two of the plates, but for having given his advice and assistance in every part with a steady and disinterested friendship. Sir Robert Strange was one of the many engravers contributing to the beauty of Hunter a great work."

Instances of the reciprocal relationships that existed between other anatomists and their artist coworkers may be recited but we are eager to mention an example that is near and familiar to contemporary medical illustrators. This is the association of a group of illustrious medical men at Johns Hopkins University with three talented artists who left their studios in Europe to come to America just before the turn of the past century. Max Brödel (1870-1941) who was the first to arrive (1894) has been titled "the greatest medical illustrator who has ever lived" by his friend and coworker Dr Thomas A. Cullen.

Upon the occasion of the seventy fifth birthday of Dr Howard A. Kelly (1858-1943) Max Brödel spoke and from this address we have taken the following words that relate to our subject. He (Dr Kelly) had a way of making little modest outline sketches when he explained his operative procedure to his illustrators. There were three of us now. Hermann Becker came in 1895 August Horn in 1898. Dr Kelly had endless patience with us. He invented diagrams to show variations of form and relationship motion pressure, tension rupture the development of a pathologic

process, the sequence of operative steps, the placing of ligatures, sutures, etc. In short, every clinical phenomenon, every operative procedure flowed in simple, eloquent lines from the end of his pencil. Few medical men can do that. What if the work was not correct. It did not matter, the spirit was there. We understood his diagrams, they were eloquent. In this way Dr Kelly taught his artist the secret of the correct conception of an illustration which is the basis of all creative drawing. This is one great debt we owe Dr Kelly. Of another debt, Max Brödel continued.

Dr Kelly always permitted the artists to make original investigations to clear up the obscure point. That meant temporary cessation of illustrative output until the question could be answered. Few authors of medical books will do that. Without his sympathetic attitude we could not have learned our trade so well.

Through the vision and effort of Dr Cullen, the opportunity to aid other artists was provided Max Brödel when the first school in the world for training medical artists was established at Johns Hopkins with Brödel as its director. It is significant that the fame of this modest artist and teacher will endure not alone because of his contributions to education and to art, but because his spirit was an investigative one and he keenly appreciated the need for close co-operation between author and artist.

REVIEWS OF NEW BOOKS

THE fourth edition of Key and Corwell's *The Management of Fractures, Dislocations and Sprains* has the same physical appearance as the third edition but many new illustrations have been added and older ones have been deleted. The book has been brought up to date and experiences gained by many workers during World War II have been incorporated.

The general principles of débridement, chemotherapy and immediate internal fixation of fractures are aptly discussed and briefly presented in a readily understandable style. The chapters which are devoted to workmen's compensation laws and the medicolegal aspects of fracture cases are well worth studying.

The discussions of fracture of the skull and brain trauma and fractures of the jaws and face are well presented by competent specialists in the fields mentioned.

The reviewer wonders whether the illustrations of the use of Kirschner wire traction through the distal third of the humerus and ulna for skeletal traction in the elbow region may lead inexperienced men who will be guided by this excellent book to attempt a method which requires skill, experience and judgment. A more lengthy discussion of its dangers and perhaps an illustration of "picture hook" traction of the olecranon, as used by Cuthbert for years might help to diminish the risk associated with this procedure.

The authors are to be congratulated on maintaining the excellent standard of this work and for keeping the material abreast of the times. It is well worth study by student general practitioner and specialist.

CARLO SCUDERI

THE influx of women into industry which began during the recent war has created a need for the book entitled *Women in Industry: Their Health and Efficiency* by Dr Baetjer who has gathered in orderly fashion pertinent information gleaned from the recent medical literature.

The following subjects which are covered in this work indicate its scope: the ability of women to work the types and conditions of work for women; sick absenteeism among women employees; accidental injuries to working women; occupational diseases; gynecological and obstetrical problems associated with the employment of women; mortality and fertility of women in relation to occupation. In a

THE MANAGEMENT OF FRACTURES, DISLOCATIONS, AND SPRAINS. By John Albert Key, B.S., M.D. and H. Earle Corwell, M.D. F.A.C.S. 4th ed. St. Louis: The C. V. Mosby Co. 1945.
PROTECTING INDUSTRY FROM HEALTH TO EFFICIENCY. Issued under the auspices of the Division of Medical Sciences and the Division of Engineering and Industrial Research of the National Research Council. By Anna M. Baetjer, Sc.D. Philadelphia and London: W. B. Saunders Co. 1945.

single chapter Dr Baetjer helpfully summarizes the above subject matter and arrives at some logical conclusions. The appendix lists some useful facts including labor laws for women and the bibliography is most complete.

In my opinion this book is of value to all physicians and a must for gynecologists and for those engaged in industrial medicine and surgery.

F. L. SATTIN

THE work entitled *Le fibro myome uterin* by J. Ducuing is based on 1300 cases personally observed of which 547 had not been previously published. The illustrations consist of many gross and photomicrographs as well as a considerable number of line drawings.

The importance of the book lies in the author's vigorous championing of radiation therapy in preference to surgery in the treatment of fibromyomas. In a series of 434 cases whose management he reports in detail 74 cases were treated surgically and 360 cases by radiation. The author states that he realizes the ideas which he defends on radiotherapy of fibromas have provoked much criticism especially from surgeons. He attacks in detail the conclusions of the French Surgical Congress of 1924 in which on the treatment of fibroids, a minor place was given to radiotherapy and a major one to surgery.

The book presents also many and complex aspects of the subject such as surgery, endocrinology, jurisprudence, experimentation, physiology and pathological anatomy. In Chapters I through VI the author presents a number of composite studies including age groups affected, menarche and menopause, fibroids and pregnancy and gross characteristics of fibromyomas. In Chapter VII he considers the present state of research and after a review of anatomy and physiology he discusses the fibroblast of the muscle fiber in the fibromatous uterus, the relationship in myomas are shown by photographs of corrosion specimens. A note on the physiology of the female genital cycle, on the sex hormones and on the synchronization of the menstrual and ovulatory cycles immediately precedes the discussion of the pathogenesis and mechanism of bleeding associated with fibroids. Treatment indications and techniques are reviewed in Chapter X. Surgical conservation of the ovary is definitely inferior in the author's opinion to radiation castration. Operative procedures on the uterus are reviewed by a series of line drawings. The author emphasizes postoperative embolism while minimizing the possibility of any late

the rectal sphincters. He states that one should always remove 15 centimeters of bowel above the tumor and 5 centimeters below. If this can be done and the rectal sphincter preserved well and good if the sphincter must be sacrificed. He favors as a routine standard procedure the abdominal plus the sacral route with preservation of the sphincter. This operation requires more time is more precise and often is followed by fistulas as compared with the domopneumoperitoneal operation in which the sphincter is sacrificed but which practically never is followed by fistulas.

The work is illustrated by excellent drawings of all the crucial steps in the operative procedures. The author belongs to the group of surgeons who advocate a wide exposure. If one wishes to avoid a structure one makes a generous incision exposes it, and identifies it. This procedure is advocated for the ureter, ves bladder, prostate, vagina, seminal vesicles, and uterus. He also advises that if any of these structures are adherent to the tumor mass, they in whole or in part should be removed *en bloc* with the tumor.

In discussing the preservation of the sphincters by preservation and anatomosis or by removal of the anal mucosa and drawing the bowel through the sphincter, he states that the "pull through" technique gives an imperfect sphincter that rarely holds liquids or gas, but does hold solids. He believes that an abdominal colectomy is preferable to a perineal one, contrary to the opinion of some American surgeons.

To everyone interested in the carcinoma of the rectum this book should prove of great interest. It is written by a surgeon of wide experience who reviews and analyzes all the recent literature on the subject.

VICTOR L. LERNMARK.

AN entirely new approach to the science of conduction anesthesia is presented in Pitkin's volume entitled *Conduction Anesthesia*. Such a complete coverage of the subject is to be found in no other single volume. The book is edited by Southworth and Hington and there are eight collaborators. It contains the author's personal approach to the science, authenticated by years of practical application, and a coverage of closely allied developments by well known collaborators. Throughout, a direct application of a knowledge of anatomy and pharmacology to conduction anesthesia is emphasized and the subject matter is presented in as simple a manner as is possible. The author states, "Block anesthesia is neither complicated nor difficult. Anyone who is familiar with the pharmacology of local anesthetic drugs and with osseous and neuro-anatomy can be successful in performing it in a very short time." He elucidates a number of fallacies in conduction anesthesia which have been perpetuated for the time of early workers in this field. Crile's work in

Conduction Anesthesia, *Clinical Studies of George P. Pitkin, M.D., F.A.C.S., F.R.C.S.* Edited by James L. Southworth, M.D., and Robert A. Hington, M.D. Philadelphia, London, Montreal: J. B. Lippincott Co., 1941.

local anesthesia, he states, was his incentive and the practice of Crile's methods made his work possible. The text is intended as a guide to the more common procedures employed by the average physician as well as a source of technical information for a physician interested in specialized fields of surgery.

The anatomy of the cranial and spinal nerves and the autonomic nervous system is completely discussed. The entire nerve supply of various organs of the body is given under a separate heading for each organ. This subject matter is arranged so that easy reference is possible when needed. The concept is stressed that the autonomic as well as somatic pathways must be blocked for successful anesthesia. The underlying principles of conduction anesthesia are elaborated and specific techniques are given in detail. There is a section on the pharmacology and toxicology of local anesthetics. The section on shock contains a basic review and a discussion of the most recent and controversial concepts of this syndrome. Directions for and discussion of the various methods of blocking all parts of the body occupy 426 pages. The author makes it clear that he prefers the simplest method when the desired result may be obtained by this means.

There is no area of the body and few combinations of complicating factors which have not been considered. Easy reference may be made to any specific nerve block desired and in each instance complete directions are given. Repetition of anatomical descriptions and techniques of injection is frequently purposefully included so that all pertinent information is present under each heading without referring the reader to previous or subsequent pages.

Sections on spinal and continuous spinal anesthesia follow. Applicable knowledge of anatomy and pharmacology variations in techniques and controlled pharmacology variations in techniques and controlled the method. Because effects may be complicated by a variety of factors, the author stresses conditions. Ability to withdraw the dose is stressed as a safety factor in reference to the continuous spinal technique. The section on refrigeration anesthesia contains modern concepts of the physiological changes incident to reduction of temperature and application to operative procedures. Methods to be used are elucidated. There is a section on therapeutic nerve block which covers the various conditions in which this method of treatment may be of value.

The excellent illustrations and drawings are per numerous and clearly illustrate every phase of the techniques and clearly illustrate every phase of the widespread described. The volume will have a The ready availability of its subject matter and completeness of coverage make it an unsurpassed reference text. The editors and collaborators are to be congratulated upon the compilation of this excellent work. We regret that Dr. Pitkin is no longer with us to receive well deserved acclaim.

WILLIAM E. PENNINGTON
RALPH M. TOWELL

THE monograph entitled *Endocrine Function of the Hypophysis* reprinted from the set *Oxford Loose-Leaf Medicine* is a compact terse yet complete treatise on a subject which still in spite of the extensive study which has been carried out on the functions of the pituitary gland remains incompletely explored and a matter for contention among investigators. The author, a well known clinical endocrinologist and research worker in the field of endocrinology has obviously accomplished a rather heroic success in sweeping together and co-ordinating up to the present day all the pertinent data concerning the form and functions of the hypophysis.

The book is divided into five parts (1) anatomy embryology and phylogeny of the hypophysis cerebri (2) cytophysiology and biochemistry of the adenohypophysis (3) biological, biochemical physiological and genetic concepts of growth (4) clinical disorders of growth and (5) cytophysiology, biochemistry and pharmacology of the neurohypophysis. Each of these sections is furnished with an exhaustive bibliography which reaches from the present day back into the early investigations of the past century thus providing for the serious student of this particular study a valuable source material.

ENDOCRINE FUNCTION OF THE HYPOPHYSIS. By Harry B. Friedgood, M.D. Reprinted from *Oxford Loose Leaf Medicine*. Edited by Harry A. Christian, A.M. M.D. LL.D. Sc.D. (Hon.) F.A.C.P. Hon. F.R.C.P. (Can.). New York: Oxford University Press, 1946.

The section on anatomy and embryology of the gland is one of the best to be found in English, being written in an authoritative and scholarly manner to lead up to the facts concerning the physiology of the organ which is described later. The section on clinical disorders treats briefly but adequately and with good illustrations, of the various endocrine syndromes which follow disease of the hypophysis. The paragraphs on dwarfism are gratifying in that the subject is handled so as to leave the reader with the feeling that he has just read about a new subject. In this, as in most of the other parts of the book, the writer's style is direct and factual, yet never lifeless or hackneyed.

With the background of information relative to the anatomy and physiology of the entire organ, the author has been able clearly to show the pharmacologic and clinical applications of this knowledge to the distinctly two separate parts of the gland, the adenohypophysis and the neurohypophysis. If the average medical school student or doctor is not entirely clear on the individual functions of these two actually separate organs, and is not entirely critical of the rational application of the commercial biological preparations of the gland, he has but to review this monograph. It is not fast or easy reading, but it is stimulating and informative. After reading it one feels that that is just about all there is to the subject.

MARCH, 1947

NUMBER 3

COLLECTIVE REVIEW

MEDIASTINAL TUMORS AND CYSTS

JOHN V. THOMPSON BS MD MS Indianapolis, Indiana

AS the experience of practically all authorities on mediastinal tumors and cysts appeared to be relatively limited because of the apparent infrequency of most of these conditions a rather extensive attempt was made to assemble the various observations and views expressed in the literature, particularly in the last 15 years during which period rapid developments have taken place in thoracic surgery

TUMORS OF THE THYMUS

In 1917 Bell discovered in 56 autopsies on patients who died of myasthenia gravis that the thymus was enlarged in 17 and that there were thymic tumors in 10. This series was increased through the addition of autopsy or operative findings in myasthenia gravis as reported in the views of Norris Blalock (21) Blalock with his colleagues (23, 24) and Poer. In the paper of Poer the series consisted of a total of 129 cases with abnormalities in 71 (55 per cent) of which 30 demonstrated enlargement or persistence and 41 presented tumors. Of the 41 tumors 37 were benign thymomas and 4 were classed as malignant (found at autopsy) to which the first malignant tumor removed at operation was apparently added. Blalock, *et al* (24) cited the collection of Llevre consisting of 67 patients with myasthenia in which autopsy findings of tumor in the thymic area were noted in 24 persistence or hypertrophy in 32 and no abnormality in 11. This writer observed that most of the thymic tumors in individuals with myasthenia were benign while those

in persons without it were malignant. Apparently since the report of Poer in 1917 2 thymomas were excised by Campbell Fradkin and Lipetz. Turnbull recorded the removal of 1 malignant thymoma. Clagett and Root (38) reported 10 thymectomies for tumor and enlargement or persistence apparently including those of the previous report of Clagett and Eaton (36) of 5 for tumor plus 1 for myasthenia gravis without tumor. Hardyman and Bradshaw explored 3 cases of myasthenia gravis and found 1 benign thymoma and 1 cystic partially involuted thymus (both removed) but were unable to find the gland in the third case. Blalock (22) recently reported 20 cases of myasthenia gravis subjected to operation in which a thymoma was removed in 2 while in the others this gland presented the picture of hyperplasia. He read a letter from H. R. Vieta during the discussion of the paper giving the results of operation on 14 patients, and it was noted that there were 3 thymic tumors in the group (There has been no attempt here or apparently by others recently to bring the autopsy incidence up to date.) It would seem that at least 6 malignant thymic tumors were observed in myasthenia gravis (143, 165). Heuer and Andrus (98) stated that there were other benign tumors not associated with myasthenia gravis which were somewhat similar pathologically although they were somewhat less frequent. Perhaps the huge tumor of Andrus and Foot (10) might be considered in this connection. Heuer and Andrus (98) further stated that benign thymomas in general were less common than the malignant ones.

Bell collected 73 cases of thymic tumor excluding the lesions associated with myasthenia gravis and leukemia which were designated as

Portion of thesis submitted in partial fulfillment of the requirements for the degree of Master of Science in Surgery in the Graduate School of the University of Illinois, Chicago, Ill.

various forms of sarcoma with lymphosarcoma predominating or were unclassified in 51 cases, 10 as carcinoma 6 as thymoma, 1 as fibroma and 5 as miscellaneous types. Crosby was able to collect 122 cases of sarcoma and 44 of carcinoma to which Decker added 40 cases plus 2 of his own for a total of 208 malignant thymic tumors. Decker also pointed out that the usual abnormalities of the thymus were benign hyperplasia of infancy hyperplasia in Hodgkin's disease, exophthalmic goiter myasthenia gravis, leucemia, and status lymphaticus. He believed that malignant tumors were rare and cited Symmer's figures of 25 malignant tumors found in 17,000 autopsies. Hesser and Andrus (98) in 1940 collected 230 malignant tumors of the thymus including the previous reviews, which included lymphosarcoma carcinoma sarcoma, granulomatous tumors such as Hodgkin's disease, teratoid and other types.

Ewing stated that the thymus gland increases in size to the age of 15 and described the simple hypertrophy in infants and Grave's disease as being due to lymphocytic hyperplasia. He discussed several groups of cysts of the thymus gland (1) those consisting of epithelial canals of embryonal type persisting with cystic formation, some associated with syphilis at times those described in Grave's disease some lined with pavement epithelium and some demonstrating polypoid masses (2) dermoid cysts, (3) cysts demonstrating invasion and distention of Hassel's corpuscles by lymphocytes—small cysts lined with cubical or flat epithelium, and (4) cystic lymphangioma, lined with endothelial cells.

Regarding primary tumors of the thymus, Ewing considered that the age incidence with other factors suggested that thymic carcinoma may be affected by disturbances in involutional processes and that certain reticulum cells may respond to infection with later neoplastic changes. He classified the primary malignant tumors into three main groups

- 1 Lymphosarcoma or thymoma—a growth of round polyhedral and giant cells. The chief source is probably the reticulum cells, although lymphocytes are present. The tumors were described as occasionally being cystic and creamy yellow or lemon colored. An encapsulated group was recognized but apparently considered less malignant. The group suggestive of the granuloma of Hodgkin's disease, those consisting of small round cells in which the reticulum was said to be missing and the class described as perithelioma were also noted by him.

- 2 Carcinoma from the reticulum cells with invasion of the surrounding tissue apparently less

active than in other carcinomas. He observed that these may be of a mixed type and difficult to determine

- 3 This group was considered as a rare spindle cell or myosarcoma and was believed to originate from the stroma but it might be a part of group 1. Ewing apparently believed that thymic round cells differ from those of the lymph nodes, but reticulum cells are the source of tumor in what is termed lymphosarcoma and that many tumors may fall in the class of granuloma malignum.

Andrus and Foot (10) noted that the greatest difficulty in classification was the unknown origin of the lymphoid type of cells, whether they were of mesodermal or entodermal origin, and classified the thymomas as follows

Nonmalignant thymomas (Thymic reticulisarcoma variety are a type.) The usual type are tumors of disarranged normal tissue elements, such as peripheral reticulum cells and central thymocytes in the lobules. Characteristic corpuscles are present although eosinophilic thymic cells are difficult to find.

Malignant thymomas

- 1 Thymocytic or lymphocytic type—composed of small round cells with dark staining nuclei, in which Hassel's corpuscles may or may not be present

- 2 Large celled or lymphoblastic type—consisting of large round to ovoid cells similar to early reticulum cells, with or without corpuscles

- 3 Thymic reticulum cell type. These are the largest and most frequent variety with cells resembling thymic reticulum cells, although they may be somewhat pleomorphic and may form ductlike structures. They are epithelial in appearance and corpuscles may or may not be present. (Schminke's lymphoepithelioma¹)

- 4 Perithelial type. These are composed of fusiform cells radially placed about vessels, there are no areas of necrosis and thymic corpuscles are minor findings.

5. Granulomatous type—Hodgkin's involvement.

6. Epithelial or carcinomatous type. In these the thymic corpuscles predominate in all stages, with a pearly appearance. Reticulum cells may form radiating cords and ductlike structures.

7. Teratoid type. All of the elements in these undergo abnormal proliferation in various degrees and there may be glandlike structures or plugs of epithelium present.

Decker stated that some believed that sarcoma and endothelioma may be of parenchymal origin

¹The respective author's own usage of the term thymoma was considered throughout the section.

He also emphasized the penepithelioma of Symmers as a separate group but did not consider the teratoma as proved at that time. He desired that the term thymoma be dropped as it was used by various writers for practically any type of thymic tumor. All malignant tumors of the thymus were considered by him to be grossly similar in that they tended to compress and surround rather than invade the mediastinal structures, they tended to be encapsulated and metastasized late, although involvement by direct extension occurred. Poor observed that the determination of the presence of thymic neoplasms depended on the location, shape, and morphology of the growth its failure to invade bone, its tendency toward extension to the pleura and pericardium and its failure to metastasize below the diaphragm. Heuer and Andrus (98) indicated that the malignant thymomas grew anteriorly with involvement of the sternum of times, and posteriorly surrounding the mediastinal structures, but that distant metastases were uncommon. He described the tumors as being usually hard and nodular but sometimes soft and vascular. Crosby stated that both sarcomas and carcinomas not only involved the adjacent organs including the sternum, myocardium, thyroid and trachea but metastasized widely—even below the diaphragm. He observed that sarcomas involved the abdominal nodes and spleen more frequently than carcinomas, but that the latter metastasized more frequently to the central nervous system. Apparently most frequent in younger individuals (10 to 42 to 70 years of age) whereas teratoid and sarcomatous types of tumors were most frequent in older individuals (40 to 50 years of age). According to Crosby, lymphosarcomas and carcinomas occurred much more frequently in males than in females.

Bell was of the opinion that the thymic tumors in myasthenia gravis were distinct, and described them as small benign tumors composed of young thymic tissue which was frequently hemorrhagic. He noted the lymphocytic foci in the muscles and believed that the abnormal thymus in this condition was due to some more fundamental disorder which was also responsible for the muscle weakness. Norris believed that the change in the gland was more of an epithelial hyperplasia than a benign thymoma and was due to an extraglandular stimulus or demand. McEachern was of the opinion that the tumors in myasthenia gravis were nearly always benign and encapsulated adeomas. He suggested the possibility of an endocrine-like dysfunction of the thymus in the condition as it was affected by other endocrine gland distur-

ances. Blalock *et al* (24) wrote that the prevailing theory regarding this disease was that there was a disturbance in the neuromuscular mechanism of transmission of impulses across the myoneural junction, possibly on an endocrine basis.

Heuer and Andrus (98) state that clinically when myasthenia gravis is present thymic tumors should be looked for as they are usually small and there are frequently no symptoms of mediastinal compression present. Regarding malignant thymomas these authors indicated that the symptoms were predominately thoracic and malignant although late external signs might appear. The course was described as rapid in malignant types and the patients usually died of suffocation. Decker wrote that in the case of malignant tumor the usual signs and symptoms of mediastinal tumor such as dyspnea, cough, pain and hemorrhage, were present and that occasionally the cervical glands were enlarged or there was a swelling in the neck or upper anterior chest. He added that the signs may be fairly silent and evidenced only by metastasis. It was also found by him that physical signs were only suggestive in one half of the cases of malignant thymic tumors. Roentgenological evidence in one third of lymph node enlargement in one third and tumor in one-sixth of the cases. Decker further observed that the duration of life was usually between 1 and 18 months after the onset of symptoms. He suggested biopsy when possible and the use of bronchoscopy as diagnostic aids. Crosby found the most common complications of malignant thymic tumors to be pleurisy and pericarditis with effusion, obliteration of the vessels of the neck, and obstruction of the esophagus and of the trachea.

Blades (18) classified thymomas as tumors of the anterior mediastinum. Benign tumors of the thymus were described by Heuer and Andrus (98) as casting a circumscribed shadow in the anterior mediastinum between the sternum and pericardium. Tumors and enlargements of the thymus are best found on the lateral x ray film according to Blalock (21). Apparently such disc shaped shadows immediately above the pericardium are suggestive of these tumors and such shadows are suggestive of the thymus and such shadows are suggestive of these tumors according to both Decker and Crosby. McEachern stated that roentgenological evidence of thymic enlargement of tumor was rare in myasthenia gravis and believed that roentgen therapy of the thymus in this condition gave inconclusive results. Clagett and Eaton wrote that of the last 55 cases of myasthenia gravis at the Mayo Clinic, 9 were found to

have tumor of the thymus on careful roentgenological examination. They believed that there was some experience at the Clinic showing that there was some improvement in myasthenia gravis following roentgen therapy. They described 2 cases in which it was thought that remissions had been induced by such therapy and which were operated on with good results. Blalock (22) in his discussion advised against the use of x-ray therapy in this connection as there were reports of poor results and several deaths. Both Decker and Haagensen pointed out that sarcoma of the thymus gland was radiosensitive but that carcinoma was not. Decker suggested x-ray therapy for palliation, particularly in lymphosarcoma.

The report of Kennedy and Moench was cited by Blalock *et al* (24), 84 patients with myasthenia gravis were observed of whom 24 died of the disease, and in whom complete remissions varied from 1 month to 15 years with an average duration of 2 1/2 years. The figures of Viets were cited there were 100 cases of the disease of which 22 terminated fatally. In this series only medical treatment was given. Blalock (22) found that the results from surgery in myasthenia gravis were not uniform but they were encouraging and there seemed little doubt that thymectomy was indicated for thymic tumor in this disease. He also believed that thymectomy was probably indicated when there was no demonstrable tumor if the patient was disabled with myasthenia gravis despite prostigmine therapy. The results were considered to be better in those not having suffered from the disease over long periods and he suggested that the operation be limited to patients with severe disease at least for the present. The indications in benign and malignant tumors of the thymus occurring in those not suffering from myasthenia gravis would appear to be the same as for mediastinal tumors in general, as noted later in the review.

Blalock (22) noted that in patients with myasthenia gravis the preoperative determination of the quantity of prostigmine which produced maximum improvement was important in the later management. Blalock *et al* (23) pointed out that it was most important to prevent respiratory infections as they cause exacerbation and some of the effect of prostigmine is lost. Prostigmine in doses of from 15 to 25 mgm. and atropine were administered preoperatively and these writers observed that the dosage may need to be increased the first few days. They found the major complications of operation to be pneumonia and atelectasis. Clagett and Eaton (36) also stressed that infections, trauma exertion, and nervous

strain be avoided preoperatively. They administered sulfadiazine and controlled the patient with prostigmine preoperatively. Oxygen, prostigmine, chemotherapy, and bronchoscopy with aspiration of secretions, if necessary were used.

Blalock (21-22) operated through an upper median sternotomy and remarked about the small amount of ether necessary for adequate anesthesia (intratracheal technique was used). The operative technique was described as starting with a longitudinal incision from the cricoid to the level of the fourth costal cartilage with separation of the sternohyoid muscles. A finger was inserted under the manubrium and both pleural reflections were pushed aside. The sternum was split to the fourth cartilage and divided transversely. The muscle and fascia at the base of the sternohyoid muscles were divided. Thymic tissue was usually found below the level of the left innominate vein, although the gland may extend to the inferior pole of the thyroid gland, and there was usually 2 lateral lobes extending under the pleura. The vessels communicated mostly with the thyroid or internal mammary vessels. The thymic mass was removed by dissection from the attachments to the pericardium and fascia over the aorta and great vessels. No drainage was used, the sternal flaps were approximated with braided silk, and then the remainder of the incision was closed. Clagett (36-38) preferred the sternal splitting approach, similar to the one described, for the usual case as it gave a good view and was extrapleural. He mentioned the use of a posterolateral approach with division of the costal cartilages and the posterolateral incision which gave good exposure but was transpleural.

Sauerbruch, whose cases were reported by others (4-235-254) was credited with the first attempt to cure myasthenia gravis (21-35). He attempted the removal of the thymic mass in 3 cases with death in the 2 later cases of tumor and failure to cure in the original case (enlarged gland) although improvement was noted. Haberer was cited for the second attempt and apparently here only involution of the thymus was present. The excision of the large tumor reported by Andres and Foot (10) apparently was the first successful removal of a thymoma, and this was considered essentially nonmalignant. Myasthenia gravis apparently was not diagnosed in the case although fatigability was noted (36). Blalock *et al* (21) first reported the removal of a cystic, necrotic, thymic tumor in a case of myasthenia gravis in 1939 the patient was followed up for some time and appeared to be essentially well. Blalock and his colleagues (23) later reported operation on 6

cases of myasthenia gravis with no roentgenological evidence of tumor but in which a persistent thymus was found in every case. Poer in 1942 believed his successful removal of a malignant thymic tumor in a case with myasthenia gravis was the first instance of such a circumstance. Turnbull also removed such a tumor but failed to influence the course of the disease. The other surgical reports were noted in the first paragraph with the exception of the thymectomy of Leriche and Jung following which there was no early improvement. It is of interest to note that in at least 2 cases operated on there was an associated hyperthyroidism (17, 34).

Clagett and Eaton (36) collected 8 cases of thymic tumor in myasthenia gravis in which operation was carried out (cases of Blalock *et al* and Campbell Fradkin, and Lipetz Poer Turnbull and Sauerbruch) and they classed the results as 2 of benefit, 2 remissions, 1 of no benefit, and 3 more such cases of tumor in which the results of their disease uninfluenced 1 case was operated on too recently for classification. Blalock (22) recently reported 2 cases in which a tumor was removed and classed the results as 1 patient considerably benefited and 1 essentially well. Hardyman and Bradshaw recorded 1 case in which removal of a benign thymoma gave benefit. Thus, excluding the first case of Sauerbruch (154) there were at least 15 benign and malignant tumors of the thymus that occurred in myasthenia gravis for which operation was carried out, and the results were described as remissions or of benefit in 8 cases too early for classification in 1 case of no benefit or influence on the disease in 3 cases, and death in 3 cases.

Blalock (22) reported 20 cases in which thymectomy was performed in the treatment of myasthenia gravis, which included the 6 cases of a previous publication (23). In this series the duration of illness was from 7 months to 12 years and the follow-up period was from 6 months to 2 years and the early 3 of little if any benefit, 5 of moderate benefit, 5 of considerable benefit, and 3 essential cures. If the 2 cases of thymoma are excluded in Blalock's series and the cases of Sauerbruch (154) Clagett and Eaton (36) Hardyman and Bradshaw Leriche and Jung and Haber and Bradshaw the total results in 23 cases without tumor but in which thymectomy was performed are 4 deaths, 5 results of no or little benefit, 13 of benefit in various degrees and 1 result which is too recent for evaluation.

If the results reported in the letter of Viets (which included 3 tumors not reported separately as to results) read by Blalock (22) are added to the combined figures for both the tumor and non tumor groups in which thymectomy was performed in myasthenia gravis, the total of the results for both groups becomes 11 deaths, 9 of no or little benefit, 28 of benefit in various degrees and 4 too recent for classification in a total of 52 cases.

LYMPHOMAS LYMPHOCYTOMAS LYMPHOSARCOMAS LEUCOSARCOMAS HODGKIN'S DISEASE

Heuer and Andrus (98) stated that there was no set classification of these tumors and that it was difficult to classify them with accuracy. These authors cited a classification of Ewing according to cell origin, namely from lymphocytes, reticulum cells, or endothelial cells of lymphoid tissue. It was considered that simple lymphomas malignant lymphocytoma, and leucemias arose from lymphocytes and that myeloid leucemia, malignant granulomas Hodgkin's disease and large cell lymphosarcomas were derived from reticulum cells. Endotheliomas were considered as developing from endothelial cells.

Heuer and Andrus discussed simple lymphomas (of which type none was noted by them) malignant lymphocytomas, lymphosarcomas, and Hodgkin's disease. Malignant lymphocytomas were considered as a clinical rather than a pathological group of tumors and included malignant lymphocytomas not otherwise designated by them, malignant lymphadenomas and possibly small cell leucemia. The basis for the group was lymphatic small cells resembling lymphocytes. Lymphocytomas were considered as moderately large tumors arising in the anterior mediastinum, extending up and through the mediastinum, surrounding the mediastinal structures, invading the organs, and metastasizing distally. The tumors were described as hard nodules resembling sarcoma of the small lymphocytic type. The third group or lymphosarcomas, was considered fairly common and the writers found 18 cases in a series of 145 mediastinal tumors. These tumors were said to arise from the mediastinal lymph glands or thymus, usually in the anterior mediastinum surrounding and compressing the mediastinal structures. Lymphosarcomas were not considered as being very invasive, although they may extend into the retroperitoneal region below the diaphragm and may metastasize. The tumors were described as hard with little necrosis and made up of multiaxial lymphoid cells with hyperchromatic

have tumor of the thymus on careful roentgenological examination. They believed that there was some experience at the Clinic showing that there was some improvement in myasthenia gravis following roentgen therapy. They described 2 cases in which it was thought that remissions had been induced by such therapy and which were operated on with good results. Blalock (22) in his discussion advised against the use of x-ray therapy in this connection as there were reports of poor results and several deaths. Both Decker and Haagenen pointed out that sarcoma of the thymus gland was radiosensitive but that carcinoma was not. Decker suggested x ray therapy for palliation, particularly in lymphosarcoma.

The report of Kennedy and Moersch was cited by Blalock *et al* (24), 84 patients with myasthenia gravis were observed of whom 24 died of the disease, and in whom complete remissions varied from 1 month to 15 years with an average duration of 2 2 years. The figures of Viets were cited there were 100 cases of the disease, of which 23 terminated fatally. In this series only medical treatment was given. Blalock (22) found that the results from surgery in myasthenia gravis were not uniform but they were encouraging and there seemed little doubt that thymectomy was indicated for thymic tumor in this disease. He also believed that thymectomy was probably indicated when there was no demonstrable tumor if the patient was disabled with myasthenia gravis despite prostigmine therapy. The results were considered to be better in those not having suffered from the disease over long periods and he suggested that the operation be limited to patients with severe disease, at least for the present. The indications in benign and malignant tumors of the thymus occurring in those not suffering from myasthenia gravis would appear to be the same as for mediastinal tumors in general, as noted later in the review.

Blalock (22) noted that in patients with myasthenia gravis the preoperative determination of the quantity of prostigmine which produced maximum improvement was important in the later management. Blalock *et al*. (23) pointed out that it was most important to prevent respiratory infections as they cause exacerbation and some of the effect of prostigmine is lost. Prostigmine in doses of from 15 to 25 mgm and atropine were administered preoperatively and these writers observed that the dosage may need to be increased the first few days. They found the major complications of operation to be pneumonia and atelectasis. Clagett and Eaton (36) also stressed that infections, trauma, exertion, and nervous

strain be avoided preoperatively. They administered sulfadiazine and controlled the patient with prostigmine preoperatively. Oxygen, prostigmine, chemotherapy, and bronchoscopy with aspiration of secretions, if necessary were used.

Blalock (21, 22) operated through an upper median sternotomy and remarked about the small amount of ether necessary for adequate anesthesia (intratracheal technique was used). The operative technique was described as starting with a longitudinal incision from the crease to the level of the fourth costal cartilage with separation of the sternohyoid muscles. A finger was inserted under the manubrium and both pleural reflections were pushed aside. The sternum was split to the fourth cartilage and divided transversely. The muscle and fascia at the base of the sternohyoid muscles were divided. Thymic tissue was usually found below the level of the left innominate vein, although the gland may extend to the inferior pole of the thyroid gland, and there was usually 2 lateral lobes extending under the plexus. The vessels communicated mostly with the thyroid or internal mammary vessels. The thymic mass was removed by dissection from the attachments to the pericardium and fascia over the aorta and great vessels. No drainage was used, the sternal flaps were approximated with bridled silk, and then the remainder of the incision was closed. Clagett (36, 38) preferred the sternal splitting approach similar to the one described, for the usual case as it gave a good view and was extrapleural. He mentioned the use of a parasternal approach with division of the costal cartilages and the posterolateral incision which gave good exposure but was transpleural.

Sauerbruch, whose cases were reported by others (4, 135, 154) was credited with the first attempt to cure myasthenia gravis (21, 35). He attempted the removal of the thymic mass in 2 cases with death in the 2 later cases of tumor and failure to cure in the original case (enlarged gland) although improvement was noted. Haberer was cited for the second attempt and apparently later only involution of the thymus was present. The excision of the large tumor reported by Andrus and Foot (10) apparently was the first successful removal of a thymoma, and this was considered essentially nonmalignant. Myasthenia gravis apparently was not diagnosed in the case although fatigability was noted (36). Blalock *et al*. (24) first reported the removal of a cystic, necrotic, thymic tumor in a case of myasthenia gravis in 1939 the patient was followed up for some time and appeared to be essentially well. Blalock and his colleagues (23) later reported operation on 6

cases of myasthenia gravis with no roentgenological evidence of tumor but in which a persistent thymus was found in every case. Poer in 1942 believed his successful removal of a malignant thymic tumor in a case with myasthenia gravis was the first instance of such a circumstance. Turnbull also removed such a tumor but failed to influence the course of the disease. The other surgical reports were noted in the first paragraph with the exception of the thymectomy of Leriche and Jung following which there was no early improvement. It is of interest to note that in at least 2 cases operated on there was an associated hyperthyroidism (17-34).

Clagett and Eaton (36) collected 8 cases of thymic tumor in myasthenia gravis in which operation was carried out (cases of Blalock *et al*, Campbell Fradkin and Lipetz, Poer, Turnbull and Sauerbruch) and they classified the results as 2 of benefit, 2 remissions, 1 of no benefit, and 3 early deaths. The writers reported, in addition, 5 more such cases of tumor in which the results were 2 patients made well, and 3 with the course of their disease uninfluenced. 1 case was operated on too recently for classification. Blalock (22) recently reported 2 cases in which a tumor was removed and classed the results as 1 patient considerably benefited and 1 essentially well. Hardyman and Bradshaw recorded 1 case in which removal of a benign thymoma gave benefit. Thus, excluding the first case of Sauerbruch (154) there were at least 15 benign and malignant tumors of the thymus that occurred in myasthenia gravis for which operation was carried out, and the results were described as remissions or of benefit in 8 cases, too early for classification in 1 case, of no benefit or influence on the disease in 3 cases, and death in 3 cases.

Blalock (22) reported 20 cases in which thymectomy was performed in the treatment of myasthenia gravis, which included the 6 cases of a previous publication (23). In this series the duration of illness was from 7 months to 12 years and the follow-up period was from 6 months to 2 years and 9 months. The results were given as 4 deaths (3 early), 3 of little if any benefit, 5 of moderate benefit, 5 of considerable benefit, and 3 essential cures. If the 2 cases of thymoma are excluded in Blalock's series and the cases of Sauerbruch (154), Clagett and Eaton (36), Hardyman and Bradshaw, Leriche and Jung, and Haberer are added the total results in 23 cases without tumor but in which thymectomy was performed are 4 deaths, 5 results of no or little benefit, 13 of benefit in various degrees, and 1 result which is too recent for evaluation.

If the results reported in the letter of Viets (which included 3 tumors not reported separately as to results), read by Blalock (22), are added to the combined figures for both the tumor and non-tumor groups in which thymectomy was performed in myasthenia gravis, the total of the results for both groups becomes 11 deaths, 9 of no or little benefit, 28 of benefit in various degrees, and 4 too recent for classification in a total of 52 cases.

LYMPHOMAS LYMPHOCYTOMAS LYMPHOSARCOMAS LEUCOSARCOMAS HODGKIN'S DISEASE

Heuer and Andrus (98) stated that there was no set classification of these tumors and that it was difficult to classify them with accuracy. These authors cited a classification of Ewing according to cell origin namely, from lymphocytes reticulum cells, or endothelial cells of lymphoid tissue. It was considered that simple lymphomas malignant lymphocytoma and leucemias arose from lymphocytes and that myeloid leucemia, malignant granulomas, Hodgkin's disease and large cell lymphosarcomas were derived from reticulum cells. Endotheliomas were considered as developing from endothelial cells.

Heuer and Andrus discussed simple lymphomas (of which type none was noted by them) malignant lymphocytomas lymphosarcomas, and Hodgkin's disease. Malignant lymphocytomas were considered as a clinical rather than a pathological group of tumors and included malignant lymphocytomas not otherwise designated by them, malignant lymphadenomas, and possibly small cell tumors of the thymus associated with lymphatic leucemia. The basis for the group was tumors of small cells resembling lymphocytes. Lymphocytomas were considered as moderately large tumors arising in the anterior mediastinum extending up and through the mediastinum surrounding the mediastinal structures invading the organs, and metastasizing distally. The tumors were described as hard nodules resembling sarcoma of the small lymphocytic type. The third group or lymphosarcomas was considered fairly common and the writers found 18 cases in a series of 145 mediastinal tumors. These tumors were said to arise from the mediastinal lymph glands or thymus, usually in the anterior mediastinum surrounding and compressing the mediastinal structures. Lymphosarcomas were not considered as being very invasive, although they may extend into the retroperitoneal region below the diaphragm and may metastasize. The tumors were described as hard with little necrosis and made up of multitudinous lymphoid cells with hyperchromatic

nuclei in reticular tissue and with destruction of the node architecture. Heuer and Andrus observed that in a few cases of Hodgkin's disease the mediastinum may appear as the seat of the disease, although it was usually involved later and they emphasized that the involvement was only a part of the general picture. These writers noted that the glands may remain discrete or demonstrate invasive qualities as a mass surrounding mediastinal structures and extending to other organs. The microscopic picture was described as a diffuse cellular hyperplasia with endothelial cells, giant cells, plasma cells, eosinophile leucocytes, and Dorothy Reed cells. Twenty nine cases of Hodgkin's disease were found in a series of 145 mediastinal tumors.

Haagensen discussed these tumors and described the small round cell lymphosarcoma (malignant lymphocytoma) as rare and as occurring in the thymic area with wide metastasis. Large round cell lymphosarcoma (reticulum cell) was considered frequent and he expressed the view that its origin was unknown—whether from the thymus, lymph nodes, or both. He stated that lymphatic leucemia involved the mediastinal nodes and that the thymus for the most part was not involved. Leucosarcomatosis was characterized according to him, by leucemic and lymphosarcomatous features. A blood picture with predominant large mononuclear cells and usually involvement of the anterior mediastinal nodes and other tissues with an overgrowth of the large mononuclear cells in the lymphatic tissues was noted. Infiltration of the adjacent organs in the mediastinum as in sarcoma was considered as differentiating this type from the lymphatic leucemia group. Hodgkin's disease was described by Haagensen as usually originating in the lymph nodes and infiltrating widely. He gave some evidence to suggest a possible thymic origin as distinct from Hodgkin's disease of other organs.

MacCallum commented on the regional character of lymphosarcoma and Boyd (27) also distinguished the small cell lymphocytic and the large cell reticuloendothelial types of lymphosarcoma.

Haagensen gave the age incidence of the large round cell lymphosarcoma and Hodgkin's disease as most often from 20 to 30 years, while small round cell types were usually found in infants. Heuer and Andrus (98) found the age incidence to be somewhat older with a frequency of 2 to 1 in males for lymphocytoma and lymphosarcoma.

Heuer and Andrus (98) found the symptoms and signs of lymphocytoma and lymphosarcoma to be similar in that there were signs of mediastinal

compression and of involvement of the organs with pain, progressive hemoptysis, occasional low grade leucocytosis, and pleural effusions. They noted that these tumors were rapidly fatal, with an average of 32 weeks from the onset of symptoms to death. The signs and symptoms of Hodgkin's disease were considered similar to those of lymphosarcoma although not so fulminating.

Blades (18) considered the lymphomas as usually occurring in the anterior mediastinum. Reby (151) suggested that mediastinal adenopathies were more centrally located in the mediastinum.

Heuer and Andrus (98) observed that the roentgenological appearance of lymphocytoma and lymphosarcoma was of a sharp or diffuse mediastinal mass. They described the appearance of Hodgkin's disease as more sharply defined and lobulated, the mass extending from the cardiac shadow up toward the neck. It was believed that in Hodgkin's disease, good palliative relief could be obtained from roentgen therapy while in the other lymphomas a temporary reduction in size might be expected.

Haagensen pointed out that secondary compressive and inflammatory changes adjacent to the tumor may confuse the roentgen picture. He stated that malignant tumors of lymphatic origin frequently have irregular hazy borders and cited Lenk's observations that lymphosarcoma was most often irregular and hazy. Hodgkin's disease was more clear cut with less evidence of infiltrative growth and the leucemic picture was usually clear cut with polycyclical outline. Haagensen found that lymphosarcomas, Hodgkin's disease, leucosarcomas, and leucemic lymphomas were often very radiosensitive although there was an occasional resistant case. He further noted that small round cell lymphosarcomas and lymphatic leucemia were not very radiosensitive, but that large round cell lymphosarcomas were quite radiosensitive, as was Hodgkin's disease for the most part, while leucosarcomatosis was moderately radiosensitive.

Heuer and Andrus (98) stated that surgery had been of no value as yet in malignant lymphocytoma and lymphosarcoma.

NEUROGENOUS TUMORS

Heuer and Andrus (98) analyzed 108 cases of these tumors in 1940. Blades (18) was able to collect 135 and considered primary nerve tumors the most important group of tumors in the posterior mediastinum. Kent, Blades, Valle, and Graham (108) recently reviewed 105 cases from the literature and 18 proved intrathoracic cases from the Barnes Hospital. Harrington (83) in 1934, re-

sorted 14 surgically treated cases of mediastinal or intrathoracic tumors termed perineural fibroblastomas, from the Mayo Clinic.

Foot reviewed and classified the tumors of peripheral nerves to indicate the histogenic position of each as follows:

Neuroma

1 Cellular (a) primitive and undifferentiated sympathogonioma (neuroepithelioma, neurocytoma) (b) incompletely differentiated sympathoblastoma (sympathicoblastoma, neuroblastoma) (metastasize on right to liver—Pepper and on left to skeleton—Hutchinson) medulloblastic—sympathetic neuroblastoma and sympathetic spongioblastoma pheochromoblastic pheochromoblastoma (c) well differentiated ganglioneuroma—some congenital—may arise from cells in lymph nodes, and some may become malignant—sympathetic neuroblastoma pheochromocytoma (chromaffinoma, paraganglioma, argentaffinoma)

2 Fibrillary (a) true fibrillary neuroma—growth of peripheral nerve fibers (b) false traumatic neuroma—only shell overgrowth with probably no axones appendiceal neuroma—Auerbach's and Messner's plexuses—inflammatory?

Tumors of the Nerve Sheath

1 Simple or specific (a) poorly or incompletely differentiated neurilemmosarcoma (malignant schwannoma) (b) well differentiated neurilemmoma of Stout (perineural fibroblastoma, neurinoma, schwannoma peripheral glioma) A type with whorls or Verocay bodies—palisading B type myxomatous with fusicellular component.

2 Compound (a) poorly or incompletely differentiated neurogenous sarcoma (b) well differentiated subterminal (cutaneous neuroma) sheath neurofibroma plexiform neurofibroma, neurofibroma (Ranke-neuron elephantiasis neurofibromatosis) neurofibromatosis (von Recklinghausen's disease) associated tumors of neurofibromatosis Pringle's—lipoma—fibroma.

3. Terminal neurogenous tumors.

In Foot's discussion it was noted that in non-myelinated fibers there were sheaths of cells similar to those of Schwann but termed Remak's fibers. Foot also commented that the sheath of Schwann has a limiting Schwann membrane, outside of which is the endoneurium which contains various structures. (Special stains are needed for identification of the structures.) It was thought that there was considerable basis for the common origin of the sheath and nerve. Foot noted that there was no reason why a pure fibroma of the nerve sheath could not occur. Concerning neurogenic sarcoma it was considered that a neurilemmosarcoma and a fibrosarcoma or reticulum cell

sarcoma occurred. Ewing's belief that most of the spindle celled sarcomas of skin and deeper tissues of the limb and trunk arose from peripheral nerves was cited as was a quotation from another source that 53 of 600 neurofibromas were found to have become malignant.

Geschikter believed that the axon myelin, and Schwann sheath were all of neurogenic origin and the endoneurium perineurium and epineurium were from connective tissue. He, as did Ewing cited Virchow as dividing peripheral nerve tumors into false neuromas arising from nerve sheaths and true neuromas arising from nerve fibers and cells. Examples of true neuromas were given as ganglioneuromas, whether occurring in peripheral spinal or sympathetic nerves as well as amputation neuromas and peripheral neuroepitheliomas. False neuromas were considered more common and as occurring in spinal or sympathetic nerves—motor or sensory—centrally or peripherally. Geschikter also commented that one school thought the false type was derived from the sheath of Schwann (neuroectodermal) and the other school from connective tissue sheaths.

Geschikter classified 2 varieties of solitary benign nerve sheath tumors

1 Differentiated—with collagen and fibrous tissue featured and areas of palisade formation of nuclei all enclosed by perineurium except at attachment. These types were considered as rarely becoming malignant and as having been termed perineural fibroblastomas, neurinomas schwannomas, neurilemmomas, and lemmomas. They were considered to be most frequent along the roots of nerves centrally particularly the roots of the cranial and spinal nerves or in subcutaneous tissue, and as occurring mostly in myelinated nerves.

2 Undifferentiated—composed of myxomatous reticulated tissue often in bundles and quite cellular. These types were considered as benign either encapsulated or not, and prone to recur or become malignant. They were considered as more frequent in deep nerves of the extremities or under the epidermis (they may be associated with von Recklinghausen's disease) and as occurring primarily in unmyelinated nerves such as the sympathetic. They have been termed fibromyxomas, fibroneuromas, and myxoid neurinomas and are seen in children or adults. Sarcomas were described as occurring in either type, but usually in the second, and as consisting of groups of plump spindle cells with large nuclei mitotic figures, and giant cells.

Apparently Verocay was usually cited for the theory of origin of certain nerve sheath tumors

from the Schwann cells, which was supported by Masson and by Stout, while von Recklinghausen was sometimes credited for the theory of origin from connective tissue which was advocated by Penfield.

In Trueblood's discussion of neurogenic sarcoma it was pointed out that extension along the nerve may be present for some distance and yet this area may appear grossly normal. It was also stressed that malignant change may occur in von Recklinghausen's disease particularly when of deep nerve origin and, also when apparently benign, the growths may recur as pathological diagnosis is difficult. An incidence of from 10 to 15 per cent of malignant change is cited in this disease. The progressiveness of the disease from childhood to adult was mentioned.

Andrus (9) traced the cells and elements of nerves in the chest from their embryologic origin. He described the origin of both the intercostal nerve fibers from cells in the gray matter and ganglions of the posterior roots as medullary epithelium. The autonomic system was considered to be derived from medullary epithelium by way of the neural crests. The Schwann sheath was also thought to be of medullary origin and the myelin of the same origin as the axis cylinder.

Andrus (9) distinguished between neurinoma (schwannoma) and neurofibroma with the former arising from cells of Schwann rather than perineural connective tissue and described 2 types: (1) a group consisting of elongated fusiform cells similar to neuroglia of the central nervous system with vacuolated cytoplasm palisading nuclei, and perhaps whorls (Verocay bodies) and (2) the Antoni type with mucoid degeneration mistaken for myxoma and usually reported in peripheral nerves. Malignant tumors of sympathetic origin were described as varying in the degree of immature types of cells and numbers present with a tendency to pseudorosette formation in the more undifferentiated types. Neuroepithelioma was discussed as being characterized by irregular columnar cells with deep staining nuclei arranged in rosettes and lined by an internal membrane. It was thought to be a primitive form of spongoblast. Neurofibromas containing ganglion cells were termed ganglioneurofibromas. No pure neurofibroma of axis cylinders and sheaths in the chest was observed by Andrus. He apparently believed that 90 per cent of the tumors in the area discussed were benign.

Scott and Palmer outlined the embryonic development of the cells of the sympathetic system as being derived from the neural crests and ventral roots. First in the series is the sympathogonia

which is completely undifferentiated (Kuntz) and later the sympathoblast which is multipotential (Bailey). Pheochromoblasts may develop from sympathoblasts and form the pheochromocytes of the adrenals and paraganglionic bodies; sympathoblasts may develop from them and form mature astrocytes (supportive tissue) or neuroblasts may develop and form the adult ganglion cells of the sympathetics. These authors classified the tumors of the sympathetic system, modified after von Fischer (170) on the basis of embryologic development with tumor types corresponding to the dominant cell types. They pointed out that tumors may contain cells of varying maturity making classification difficult. Their classification follows: (A) completely undifferentiated—sympatheticoblastoma (1) tumors of migratory cells and sympathogonia and (2) sympathoblastoma, (B) incompletely differentiated (1) sympathetico-neuroblastoma (2) pheochromoblastoma, (3) sympathetico-blastoma and (C) completely differentiated (1) ganglioneuroma (2) pheochromocytoma, and (3) astrocytoma.

These writers described a tumor containing sympathogonia (rounded, small, deep staining nuclei) and sympathoblasts (larger vesicular nuclei) arranged in lobules and sometimes in rosettes.

Schaffner Smith and Taylor described a ganglioneuroma immaturum and 2 other ganglioneuromas of the mediastinum and while the cells were not mature they were thought not to be undifferentiated as sympathoblasts or neuroblasts. These authors stated that the majority of such tumors arose from the sympathetic chain, or anlage, and emphasized that multiple sections from different areas may show variability and even one small malignant region. Two sympathetico-blastomas were cited from the literature.

Bohrer and Lincoln collected 9 cases of ganglioneuroma and other such types of tumor in the chest of children and added 1. They apparently thought that neuroblastoma was usually found in children and cited instances of both malignant and benign tumors in the same person.

James and Cnitis collected 33 cases of mediastinal ganglioneuroma and added 1 in 1941. They considered the neuroblastoma the most common type found in children particularly in the adrenal gland, and thought that true ganglioneuroma was rare in children and benign in its early development. It was believed that there was a low tendency toward malignancy in these tumors and the older the patient the more apt they were to be benign.

Heuer and Andrus (98) pointed out that tumors may arise from any of the nerve elements occur-

ring in the thorax as well as from their intimate connective tissue elements. They also considered the hypothesis that in embryologic development cell rests may be left during early migration or carried outside of the central nervous system to explain the origin of some of the tumors such as those of sympathetic type and neuroepitheliomas.

They (98) considered that neurofibromas arose from connective tissue with degenerative or sarcomatous changes in some and that they usually occurred singly in the chest. These tumors were noted to be of all sizes in all ages and 77 per cent were found in females in a series of 20 collected cases, to which these authors added 1. The ganglioneuromas were considered as originating in sympathetic ganglia, frequently in the upper posterior mediastinum. They were described as encapsulated and firm, but they may have a dense shell with a soft center and be relatively vascular with lobulation on the cut surface. Microscopically fibrous tissue and medullated and non-medullated fibers were noted and ganglion cells spersed. Among 68 cases the age of the patient was stated in 36 and 74 per cent of the cases occurred in children under 10 years of age—females predominated 3.2. Neuroinomas (schwannomas) were differentiated microscopically from fibromas and considered of ectodermal origin. They were described as nodular enlargements of a nerve or nodules of various sizes projecting from a nerve, and of 2 microscopic types as noted in the discussion by Andrus (9). Neuroinomas were noted as occurring more often in peripheral nerves and the spinal canal than in the thorax. 19 cases were reviewed.

Kent, Blades, Valle, and Graham stated that the differentiated tumors described by Geschikter (neurilemmomas) were the principal type found in the thorax and originated most frequently in the intercostal nerves. The ganglioneuromas were the next most frequent type and if these contained considerable fibrous tissue they believed that these might be termed ganglioneurofibromas. It was also observed that certain of the tumors presenting the picture of neurilemmomas may on other sections demonstrate ganglion cells.

In a series of 105 cases of intrathoracic neurogenic tumors collected from the literature by these authors (108) the tumors in 39 cases, or 37 per cent, were malignant. The authors noted that the neurogenic tumors arising within or close to the mediastinum were less malignant than those occurring in the chest away from the mediastinum. Examination of the data concerning their collection of neurogenic tumors in the mediastinum

showed that of 74 there were 59 (79.7%) benign and 15 (20.3%) malignant, whereas of the 2, apparent chest wall tumors 11 2 per cent were benign and 88.8 per cent malignant. Further analysis of the paper revealed that in the collected cases of mediastinal tumor in which the age and sex were given there were 37 males and 29 females. The average age in the 55 benign cases was approximately 26 and in the 15 malignant cases it was about 17 years.

These authors (108) noted that neurogenic tumors are the most common ones arising in the posterior mediastinum or posterior part of the superior mediastinum and found only 2 (?) in the anterior mediastinum in the literature. Blades found that practically all of these tumors occurred in the posterior mediastinum. His collected neurogenic mediastinal tumors were classed as neurofibromas in 22 cases, ganglioneuromas in 70 neuroinomas in 19 and perineural fibroblastomas (all primary nerve tumors) in 24 cases.

Apparently most authors (9 98 108 152) thought that in the majority of cases of neurogenic tumors the onset occurred with various signs of neurological involvement, and that signs of mediastinal pressure occurred late but were not too common. Heuer and Andrus (98) pointed out that the benign tumors may be asymptomatic or the symptoms may begin during a respiratory infection and they may even be those of a respiratory infection. They previously noted (11) that intercostal pain possibly suggested a neurofibroma, whereas when a Horner's syndrome was present early a ganglioneuroma might be considered although the various types of mature tumors can not be distinguished clinically (9). Schaffner Smith, and Taylor believed the most characteristic symptom to be a dull intercostal pain and noted that these tumors may be of the Pancoast type, with or without the syndrome. Harrington (83) believed that a clinical characteristic was the relatively few symptoms for such large benign tumors, but that severe intercostal pain was a distinguishing feature if they became malignant. He found that the average duration of symptoms in his cases was 4 years and that the most common symptom was dyspnea. These tumors have occurred as hourglass tumors of the spine arising in or adjacent to the intervertebral foramina and extending through it with signs of spinal cord compression (71 98, 108).

Harrington (83 85) described the roentgenological findings in nerve tumors as consisting of sharp borders even if lobulated and located in the posterior mediastinum with or without pressure erosion of the ribs. Those in the foramina may

demonstrate erosion of the pedicles. Later erosion of the lamina, enlargement of the foramina and possible widening of the intercostal spaces. He distinguished the destruction of the infiltrative type with irregular bony damage in the malignant lesions from the erosion of the atrophic type in benign lesions. Heuer and Andrus (98) pointed out that such densities were suggestive but not proof of the type present. Kent, Blades, Valle and Graham were of the opinion that the tumors were usually single in the thorax and that a lobulated appearance suggested rapid growth and malignancy. They also stated that effusion was not proof of malignancy and that neither benign nor malignant tumors of this group responded to x-ray therapy.

Schaffner, Smith and Taylor described the intrapleural thoracoscopic appearance of neurogenic tumors as a thin, loose pleura without inflammatory reaction covering a smooth gray spherical mass.

James and Curtis writing about mediastinal ganglioneuromas in particular expressed the view that the prognosis was good in operable tumors but depended to some extent on the degree of differentiation of the tumor. Kent, Blades, Valle and Graham thought that intrathoracic neurogenic tumors should be removed because of the high incidence of malignant change if for no other reason. Harrington (83) believed that the high incidence of benign tumors in his operative series was due to early removal and stressed early removal because of the danger of malignancy or increased size. The only malignant case in his series recurred in 2 years with death.

This author (83) used an approach directly over the tumor as also advocated by others (98-108) which was usually of the posterolateral periscapular type with subperiosteal rib resection and division under the erector spinae muscles. He found that the tumors were usually surrounded by a vascular capsule. The mass was separated from the lung and adjacent structures. Attention to intercostal vessels and suture of the damaged lung were stressed. Hourglass types were best removed in one stage, and if possible the intraspinal portion was removed first to relieve the pressure symptoms. A laminectomy approach was frequently used (98-108). Wide removal of nerve roots entering or attached to a neurogenic sarcoma was advocated by Trueblood because of the microscopic extension along an apparently grossly normal nerve. Blades and Dugan (19) reported a case of a neurofibroma on the left vagus nerve with 2 likewise located on the thoracic sympathetic chain in a case of neurofibromatosis all

were resected with no ill effects and the recurrent laryngeal nerve was spared.

Heuer and Andrus (98) collected the results in 108 cases. They found 21 neurofibromas of which 4 were noted at autopsy, 17 were operated on and 29.4 per cent of the patients died while 70.6 per cent recovered. Of 68 cases of ganglioneuroma 14 were found at autopsy, 51 were operated on and 31 per cent of the patients died while 69 per cent recovered. (The incidence of hemorrhage and shock in the latter group of deaths was noted and more attention to the pedicle is suggested.) Of 19 cases of neurinoma (schwannoma) there were 4 found at autopsy, 15 were operated on and 1 of the patients died while 14 recovered. Among the many cases of intrathoracic neurogenic tumors analyzed by Kent, Blades, Valle, and Graham, there was a mortality of apparently 30 per cent, which was about equally divided between operative and nonoperative deaths.

DERMOID CYSTS AND TERATOMAS

Gordon in 1825 apparently was the first to describe dermoid cysts and teratomas at autopsy. Boyd (28) stated that teratoid tumors and lymphomas occurred in about equal numbers in the anterior mediastinum. According to Blades these tumors were twice as frequent as any other in the mediastinum except lymphomas which were noted more often.

Hertzler collected 72 cases plus 1 of his own in 1916. Kerr and Warfield increased the number to 138 in 1928. Hedblom's notable paper written in 1933 consisted of an analysis of 185 reported intrathoracic cases to which he added 6 personal ones. Houghton later added 24 cases to Hedblom's series. Heuer and Andrus (98) including their own cases, brought together 217. The latest review was that of Rusby of 1944, in which he considered a total of 251 cases. There have been numerous reports of which some of the more recent ones were of particular interest. (48) Harrington (87) has reported one of the largest series from a single clinic, consisting of 16 cases.

Hedblom stated that the consensus of opinion at that time was that congenital cystic tumors which contained epidermal derivatives were usually termed epidermoids or dermoids, those demonstrating derivatives of mesoderm were called dermoids or teratomas, and those that consisted of elements of all 3 germinal layers were usually labeled teratomas. Hertzler was able to collect 18 reports of those he considered the epidermoid type and 25 with two or more germ layers represented. Phenister, Steen, and Voldenauer added 22 cases to Hedblom's group, and found that in 1

series of 206, 162 were of the dermoid variety and 46 were of the teratomatous type. Smith and Mills differentiated between dermoid and teratomatous groups, more or less on the above basis. MacCallum denoted dermoids as simpler forms of teratomas containing essentially derivatives of ectoderm, and discussed epidermoid wens at the extreme end of the scale. Boyd (27) apparently regarded dermoids as derived of ectoderm and teratomas as derived of more than one germinal layer. Harrington (82) apparently favored grouping all the tumors of the group derived in various degrees from all three germ layers under the term *teratoma*, with a subclassification. The latter derivation of the group was also considered by Rusby (151) who subdivided the tumors into *teratomas of the dermoid type* (simple cystic variety) and *solid teratomas*.

A number of cases were reported as apparently originating in the thymus, according to Heuer and Andrus (98). A probable origin was given by Hedblom as in the region of the branchial clefts, and this author noted cases with the tumor pedicle attached to the thyroid and thymus glands as well as to other areas of the mediastinum. He also cited these two theories: (1) development from the same host embryo and (2) origination from an independent embryonal anlage such as a parasitic fetus occurring as a fertilized polar body or independent blastomere. He noted that some believed that only teratomas developed according to the second theory. Rusby stated that earlier authors tended to consider dermoids as of different origin than teratomas. They considered some as inclusions that resulted from embryonic fissure closure. This was thought to be an explanation for the occurrence of presternal dermoids with no connection to the mediastinum although some occurred as hourglass tumors through the sternum. Because there were so many borderline cases between pure dermoid (ectodermal?) types and teratomas of 3 germ layers in the literature, Rusby believed that both have a common origin. Boyd (27) apparently subscribed to the theory of inclusions of dermal tissue in the case of congenital dermoids as distinct from teratomas. He considered the premise that the latter were a product of the parthogenetic development of a segregated early germ cell. A similar view was held by MacCallum. The conception was extended further—the first segments of the blastomere were totipotent (develop near fetus) while the latter segments were multipotent and did not result in such a complete development (27). Ewing apparently gave credence to many of the different theories of origin, according to the loca-

tion and structure of the tumors. He noted that the conception of specificity of cells in germ layers was undergoing reconsideration and that the theory of a budding process was being given more consideration (budding or pinching off from early embryonic structures). The influence of organizer substances upon the development of cells in this connection, as summarized by Schwarz and Williams will be given later.

Hedblom described the structure of his class of epidermoid cysts as consisting of a cyst wall lined with stratified squamous epithelium with a stratum corneum with or without glandular tissue of ectodermal origin and containing products of ectoderm in which there may be various degrees of degeneration. He considered dermoids as demonstrating lobulation or being multicystic and presenting areas of thickening plus mesodermal elements such as cartilage, bone, teeth, and muscle. Teratomas were defined as being more or less solid and also containing derivatives of ectoderm—some of the more complex tissues resembling the pancreas, intestines, and thyroid gland with occasional organized arrangements of tissues suggesting coils of intestine, the above formations, and appendages being present. In a total of 184 cases analyzed by Hedblom there were 96 of epidermoid type, 50 of dermoid type and 38 of the teratomatous variety. Harrington (80) reported an unusually well differentiated organoid fetal-like tumor. This writer (82-87) also suggested that if enough sections were made derivatives of more than one germ layer would be found in this group of tumors. Rusby pointed out the frequent presence of a ridge or protuberance from which hair grew and which often contained cartilage in the simpler dermoid variety. He believed that this type was normally enclosed in a fibrous capsule with a pedicle and noted that there may be clusters of cysts. MacCallum mentioned the hair-bearing thickened patch and also pointed out that such complicated ectodermal elements as derivatives of the eye and central nervous system may be present. Also the thick, often brownish fluid containing fat and cholesterol crystals was noted by Phemister and his colleagues. The size of the tumors varied from that of a pigeon's egg to a size weighing 6,000 gm. or a capacity of 4 quarts or more, according to Hedblom. Heuer and Andrus (98) noted that the solid types were less frequent than the more cystic variety.

Rusby found in his review of the literature that the solid teratomas differed from the cystic dermoid types in their tendency toward malignancy. In the extensive group studied 70 per cent of the malignant tumors arose in the solid types and 30

per cent in the dermoid types. There were 27 malignant tumors among the 209 cases analyzed, or 12.9 per cent. In Hedblom's collection (185 plus 6 personal cases) there was malignant degeneration into carcinoma, sarcoma, chorioepithelioma, and other types in 17 cases, with metastasis in 8 cases.

Doran and Lester cited an incidence of 80 per cent for the benign types of these tumors and considered that those possibly malignant from the start occurred mostly in children, whereas those appearing late occurred in the cancer age. Three of Harrington's (87) 16 cases were malignant, of which 2 were squamous cell carcinomas occurring in dermoid types and the other case was an adenocarcinoma in a teratoid type. There were 5 of 13 cases of Heuer and Andrus (98) which had become malignant at the time of operation. Graham (67) stated that the incidence of malignancy in his series of 12 cases was 41.6 per cent. Chorionepitheliomatous proliferation in a teratoma was described by Frank, although the case did not rest on too secure a footing in that account. Rusby called attention to the significance of the Asheim-Zondek test in this connection, in the absence of pregnancy and of testicular teratoma.

In a series of 233 collected cases, Blades noted that only 3 of these tumors were in the posterior mediastinum, while the others were apparently located in the anterior mediastinum. This was about the same distribution as described by others (90, 98, 100). Schwarz and Williams expressed doubt that any dermoid tumor has been proved as originating in the posterior mediastinum. Harrington (87) described the usual origin of these tumors as in the region of the base of the great vessels and pericardium. They frequently were noted adjacent to the anterior pericardium (98). Hedblom observed that in 176 cases, 13 tumors were between the mediastinal pleura and behind the sternum (retrosternal); 19 presented in the suprasternal notch or from behind the sternoclavicular joint (cervicosternal); and the remainder originated in the anterior thorax generally and extended into either thoracic cavity (anterolateral thoracic). Rusby called attention to those situated preternally with no connection to the mediastinum and to those with hourglass connections through the sternum. Intrapericardial teratomas were described and some as probably originating in the diaphragm were noted (15, 62, 87, 90).

Rusby noted no particular sex predilection. Among the 171 cases of Hedblom's collection in which the sex was stated, there were 70 males and 91 females. Hedblom also found that the majority of cases were observed, operated on or noted at

autopsy before the age of 30, and, among 171 cases, there was only 1 patient in the sixth decade. There were 26 cases in his series in which the patient was under 12 years and some cases were found in patients as young as 3 to 4 months. Among 174 cases analyzed by Rusby there were 68 patients between 20 and 29 years of age, 7 between 10 and 19, and 37 between 30 and 39. Heuer and Andrus (98) found that in most cases the patients were observed in the third decade and only 5.5 per cent of the tumors were noted in patients under the age of 12.

Heuer and Andrus (98) described the tumor as growing slowly with symptoms appearing early before puberty. They also commented that the majority of cysts causing symptoms were of the lateral thoracic variety and that symptoms implicating involvement of local structures were less frequent than the general ones due to residual pressure in the mediastinum. Carlson stated that a feature of teratoid tumors was the absence of symptoms for a long period. Hedblom noted that the onset of symptoms was insidious in about 75 per cent of the cases and abrupt in many of the remainder, some cases being symptomless and discovered by examination. He observed that the duration of symptoms to autopsy or operation in 100 cases was under 6 months in 37, from 6 months to a year in 22, from 1 to 3 years in 34, and from 5 to 10 years in 18. In the same analysis, hair was expectorated by at least 26 patients, with fatty or sebaceous material and cholesterol crystals noted in several. Bulging of the chest wall in 33 patients and tumor of the neck in 19 were also mentioned in this analysis of the older case reports. Harrington (87) thought the most common features of these tumors were the intermittent symptoms with gradual progression and the association with respiratory infections. He also noted that this type of tumor was the only one in the thorax which may have a pathognomonic clinical symptom—the expectoration of hair in dermoids. Rusby believed that a palpable mass occurred late although other signs or symptoms may be mild, and described the other physical findings, when present, as signs of a mass in the chest and its complications.

Episodes and complications occurring in the course of these tumors were described by Rusby as growth with subsequent pressure effects, bronchocystic fistula (with or without infection), rupture into adjacent structures, adherence to adjacent structures, and the development of malignancy. Adhesions in some instances were considered to be due to the irritation of constant pulsation from vascular structures. Rusby suggested

that vigorous anterior pulsation of the chest, persistent tachycardia, and a right axis deviation of the electrocardiogram might indicate adherence of the tumor to the pericardium. Infected cysts may enlarge with pressure effects or rupture into the pleural cavity (empyema) or bronchus with the expectoration of foul sputum, hair and blood and thus simulate the picture of abscess or another suppurative process. It was also emphasized by Rusby that the cysts may be infected, in the absence of fistula, via the blood and lymph streams. Heuer and Andrus (98) pointed out that infection was the most common complication. One explanation of the enlargement was offered by Hertzler—an irritation of chemical nature. Hedblom noted that some of the complications may even obscure the picture of tumor. The pain was considered more prominent progressive and severe in malignant cases (82).

Rusby cited authoritative sources for the statement that an irregular, lobulated, defined mass in the anterior mediastinum on the roentgenogram was suggestive of teratoma in contrast to a rounded dermoid. He noted that a pedicle was seen on an occasional film and emphasized the use of lateral and oblique films in identifying calcified areas. Also an air fluid level in the case denoted a fistula to an air passage. Fluoroscopy is of aid in this connection and in identifying the relationship to adjacent structures, according to Rusby. Others have noted that lobulation was suggestive of the more solid teratomas (46, 141). Harrington (87) pointed out that one of the difficulties in x-ray diagnosis was interfering inflammatory changes. Phemister, Steen and Volderaner observed a shifting fluid level (line) without air in the cystic types, due to a layer of fat floating on aqueous fluid, which was confirmed by examination and analysis of a surgical specimen. Evidence was cited (151) that roentgen therapy did not affect even the malignant teratomas.

In a group of 209 deaths analyzed by Rusby there were only 9 or 4.3 per cent, in which the tumor did not contribute to the death and in 8 of these 9 the tumors were of the dermoid variety. For 47 patients who had had no previous active treatment and who died, the history varied from 14 years to 2 weeks, with an average of 1.8 years, and included both benign and malignant tumors. Heuer and Andrus (98) noted in a review of 217 cases that the 47 untreated patients all died of the disease. They mentioned 1 patient followed up for 44 years from whom the tumor was not removed. Surgical treatment was required for the prevention or relief of complications (90, 151) and the presence of same adversely affected the results of

treatment according to Hedblom (90). Harrington (82) stressed the removal of these tumors. Hedblom cautioned against simple drainage in the apparently noninfected cysts because of the added risk from the consequent infection and adhesions as well as the poor results obtained. Heuer (11, 95) advised a 2 stage operation for infected tumors with drainage to clear up the infection before removal as it was better than risking the infection that might follow primary removal. He warned against drainage of defects left by the excision of noninfected dermoids. Rusby pointed out that partial removal and marsupialization could be used if the tumor were too adherent for removal or the patient's condition poor and perhaps later removal could be completed with the benefits of reduced size and infection even though there are possibilities of sinus formation or malignant change in the remaining portion. He thought the transpleural approach was best if infection were feared or if the neoplasm were of a large size. For upper retrosternal tumors he suggested a transverse cervical collar incision with splitting of the sternum as recommended by others (82, 90) whereas the trapdoor incision was considered of value for the thoracic substernal location except for the lateral thoracic type. Harrington (82) preferred the posterior approach in most instances because of better exposure and Graham (67) suggested the inframammary approach especially in women for cosmetic reasons.

Bastinelli was credited with the first surgical removal of a dermoid cyst with cure. Hedblom noted that of 99 patients operated on there were 47.4 per cent cured, 32.3 per cent improved although with a complicating sinus, and 16.1 per cent died. The greatest cause of poor results and death in these cases was infection such as empyema and pericarditis.

Heuer and Andrus (98) reviewed the results in a total of 217 cases of which 32 were discovered at autopsy, 47 of the patients were untreated and died and in 8 the results were not known. The other 130 patients were subjected to various operations. One child died at operation in which drainage was attempted of an empyema resulting from a ruptured cyst. In 2 cases the cysts were exposed and aspirated with 1 death and 1 failure. Five patients were inoperable, 3 with malignancy, 1 died 13 days after exploration and 1 patient recovered from operation but died of the disease. Drainage or marsupialization was done in 34 cases with 9 deaths but only 5 cures. Partial resection was carried out in 12 cases with 2 deaths and 5 cures. Total excision was done in 76 cases with 8 deaths (10.7%) and 68 cures (89.3%) in con-

trast to a mortality of 26.5 per cent and cure in 15 per cent following drainage operations, and a mortality of 16.6 per cent and cure in 41 per cent following partial resection.

In the recent analysis of Rusby there were 31 patients subjected to rib resection and drainage as the only procedure. 13 were benefited, 14 died and for 4 the results were not stated. Rusby thought a number of cases in this group were collected from the older literature and mistaken for empyema. There were 15 patients treated only by partial removal and marsupialization, 9 were benefited, 4 died, 1 had an unsatisfactory result and for 1 the result was not stated. Complete removal in one or more stages was performed in 60 instances, 53 patients were cured although some small tags were left, 4 were benefited but had fistulas, and 3 died. There was no case of malignancy which was cured that was known to Rusby.

In Harrington's (87) published series of 16 cases, of which 3 were malignant, 13 patients were living but 2 did not recover from the operation. There was a complicating empyema in 5 cases, mediastinal abscess, osteomyelitis of the ribs, pneumonia, and embolism were also mentioned. Graham (67) removed 7 benign tumors without mortality.

BRONCHOGENIC CYSTS—CILATED EPITHELIAL CYSTS

Hare was cited as not finding any cysts of this type in 600 mediastinal tumors reviewed prior to 1899. Alford collected 10 cases (2 described as in the pericardium) and added 1 in 1937. Heuer and Andrus (98) were able to collect 25 cases of ciliated epithelial cysts of the mediastinum and added 1 in 1940. Brown and Robbins (31) discussed 12 cases in which operation was performed between 1934 and 1943 at the Massachusetts General Hospital. Thornton and Adams (3) published 3 surgical cases. A few other isolated cases were reported recently (35, 69).

Brown and Robbins believed such cysts were congenital malformations of tracheobronchial origin but doubted if all were of pure bronchogenic origin. The theories of development as given by Carlson were diverticula of the entoderm and mesoderm from the foregut, secondary budding of the tracheal anlage or later abnormal division of the respiratory buds, or imperfect closure of the communication between the trachea and esophagus. Heuer and Andrus (98) held a somewhat similar conception. Freedlander and Gebauer, among other premises, commented on the potency of a given germ layer—entodermal cells of the foregut may become separated which might pro-

duce cysts even if not included in the respiratory bud—and mentioned that the early foregut was lined with ciliated epithelium. Tracheobronchial diverticula have been discussed as examples of similar forms of abnormal development in this connection (3, 12, 58). These cysts are derived of mesoderm and entoderm, according to Carlson.

This writer (35) described the cysts as containing any of the bronchial elements. A ciliated epithelial lining with a wall which may contain such elements as mucous glands, fibrous tissue, elastic fibers, smooth muscle, cartilage, nerves, and vessels may compose the structure of these cysts, and frequently a milky fluid is found in them (3, 11, 35, 98). Adams and Thornton (3) noted that in some the epithelium may be absent or atrophic and the fluid contained under pressure. Greenfield and Touroff described a case of a thin walled cyst lined by columnar epithelium and containing crystal clear water, possibly of a different origin. Freedlander and Gebauer noted the theory that if cysts were developed before the fifth generation of respiratory budding fluid was contained, but if formed later air was present. These authors also differentiated between an accessory bronchogenic form with a tracheobronchial communication and an aberrant closed bronchial form. Brown and Robbins noted that some of the simpler cysts might be of pleural or pericardial origin.

Carlson found that these cysts were usually less than 5 cm. in size and apparently originated in the posterior superior mediastinum. Other authors described them as commonly located in the region of the trachea and major bronchi, usually on the right side (3, 58, 98). Blades classified bronchogenic cysts with other cysts in the anterior mediastinum. Heuer and Andrus (98) pointed out that such cysts may be found along the esophagus, particularly its lower portion. Brown and Robbins described several cysts intimately associated with the esophageal musculature and noted that they may be anywhere in the mediastinum.

Carlson expressed the opinion that bronchial cysts produced symptoms early in life, before becoming large, by their effect on the respiratory passages. Heuer and Andrus (98) indicated that a number were asymptomatic but the presence of others was suggested by signs of mediastinal pressure or the development of infection. Adams and Thornton pointed out the incidental finding of these cysts on x-ray films and stated that their course depended on their size and location. In 1 of their surgical cases the cyst was infected by coccidioid-like organisms. Freedlander and Gebauer noted that accessory types of congenital

malformations with tracheobronchial communications were more apt to produce clinical signs than the aberrant types, although the latter may become infected through the blood and lymph channels. Brown and Robbins observed that the presenting symptom was usually pain followed later by the other signs of a mediastinal tumor and that expectoration of foul sputum may occur in those infected cysts which communicate with the tracheobronchial tree. They found that the duration of symptoms in their review was from 1 to 25 years.

Robbins described the most important roentgenological sign as a smooth round or ovoid shadow anywhere in the mediastinum without evidence of bony erosion or calcification. He believed that if the density was beneath the carina and there was evidence of tracheal attachment, or of intramural extramucosal involvement of the esophagus, this supported the impression. In addition to the use of conventional x ray films, fluoroscopy and contrast media he suggested the use of laminograms in locating the cysts and demonstrating changes in adjacent tissues. It was further stated by him that there was less inflammatory reaction around infected cysts than in the picture of lung abscess although a fluid level may be present.

Freedlander and Gebauer believed it was impossible to predict the risk incurred by the presence of these cysts. Because of the difficulty in differentiation from other tumors and cysts Heuer and Andrus (98) thought that the cysts should be removed. In addition Adams and Thornton (3) thought exploration and excision were indicated because of the dangers of complications such as enlargement with pressure symptoms and infection. They also noted that partial excision with destruction of the remainder was indicated if complete removal was dangerous, but they avoided drainage unless infection was present, because of sinus formation. Brown and Robbins believed that, as the frequent cause of symptoms was infection which increased the technical difficulties, delay until its appearance increased the risk. They likewise favored removal when possible as the diagnosis was made with the tumor out and the operation was usually technically easy and safe.

In the series that Brown and Robbins analyzed there were 10 clean cases of cysts 7 cysts were removed with cure of the patients, 1 cyst was partially excised with cure and 1 was aspirated with complicating empyema. The last patient was cured after a thoracoscopy. There were 2 infected cases, 1 of the patients being well after drainage

and removal of the cyst, and the other still draining 6 years after marsupialization. In the collected cases of Heuer and Andrus (98), many of the cysts were found at autopsy and in 12 cases operation was performed. In 8 of the 12 cases the cysts were removed—5 were excised in one stage and 3 were taken out after preliminary drainage but in the other 4 cases only drainage or partial removal was carried out. All 12 patients recovered although 1 had a fistula.

Freedlander and Gebauer pointed out that *accessory and aberrant pulmonary lobes* may occur in the mediastinum or be attached to its structure by a stalk, although the aberrant types were frequently located on the left between the lower lobe and the diaphragm. Most aberrant lobes and cysts were found at autopsy in infants, according to the writers. Accessory lobes were considered as behaving as other lobes but possibly being more susceptible to pathological processes. Aberrant lobes were described as containing dilated bronchial radicles, epithelial lined cysts, cartilage, smooth muscle, and little alveolar structure with the blood supply from the thoracic aorta and the return to the azygos vein along the stalk. Their origin was suggested as similar to that of the cysts just discussed and they may have a similar course. Accessory types were considered to be more amenable to roentgenological and other means of diagnosis than aberrant types which present no typical picture. The writers noted that such malformations may cause symptoms because of location size pressure from growth and resultant pleural effusions, or because of becoming infected like cysts. They described 2 cases of aberrant lobe in the region of the mediastinum, one of which was surgically removed. Harrington (81) discussed the removal of a cystic azygos lobe from the posterior mediastinum.

GASTROENTEROGENOUS CYSTS

Roth was credited with reporting a case of cyst lined with intestinal epithelium in the thorax and another in the abdomen in 1881 and as quoting 2 similar cases. Mixer and Clifford reported 2 cases of gastrogenic cyst in 1929. Poncher and Miles described in 1933 a case of multiple gastroenterogenous cysts in the mediastinum and abdomen with intestinal diverticulum and ulcer. Brass was cited as reporting 1 case and having collected 3 cases of cysts lined with intestinal mucosa with associated intra-abdominal cysts. Black and Benjamin reported a case in which it could not be determined whether the thoracic cyst was of gastrogenous or enterogenous make-up and there was an accessory intestinal pouch in the mesen-

tery, containing an ulcer and communicating with the jejunum. Boess and Seydel are credited with cases of peptic ulcer in gastrogenic cysts with perforation into the lung and hemorrhage. Ladd and Gross described 2 cases of intrathoracic gastrogenic cysts. Nichols reported a case of gastric cyst in the mediastinum previously treated for empyema by mistake. He analyzed 10 cases of gastrogenic cyst of which 1 contained both gastric and esophageal mucosa and another with ciliated respiratory epithelium in addition to gastric mucosa. In addition to these 10 cases in his collection there was 1 intestinal cyst (Brass) and 1 cyst composed of tracheal and esophageal elements. Schwarz and Williams observed 3 cases of thoracic gastric cyst 1 of which contained functional mucosa and including their own, were able to analyze 5 collected cases with evidence of secretory function in the cyst, and 7 with no activity some of which contained respiratory as well as intestinal lining. Carlson recently reported the excision of a gastric or gastroenteric cyst in this location.

A gastric mucosa containing parietal, chief, and goblet cells surrounded by 3 layers of muscle with the outer and inner strata running in the same direction was described in gastrogenic cysts, and even Brunner's glands were noted (155). Calcification in the wall and pedicle attachment to the mediastinum were also observed. Varying degrees of destruction of the mucosa and wall from pressure, inflammation or perhaps from digestive juice were pointed out (144). Vagal nerve elements were found in the case of Brass.

The pinching off of buds or diverticula from the foregut, intrathoracic vestiges of the omphalo-mesenteric duct, specific endodermal germ cells of esophagus capable of further development, and fetal inclusions were offered by various authors as explanations of the origin of these cysts (17, 35, 133, 144). Schwarz and Williams believed that the mechanism of origin of gastrogenic cysts was

with all others on the right, when position was mentioned in the reports (133, 155). Carlson commented that the onset of symptoms occurred early in life and that all the reported enteric cysts were found in early infancy. Schwarz and Williams also found that these cysts were manifested early although one of their gastric cysts was in a patient 23 years of age. In the 12 cases analyzed by Nichols, there were only 2 patients over the age of 3 years.

Schwarz and Williams felt rather certain that gastric cysts with functional secretory activity could be distinguished more readily and differentiated from gastroenterogenous cysts of mixed make-up by the more pronounced symptomatology such as pain and pressure symptoms in the former. They noted the presence of skin excoriation in the group with secretory activity when they were drained and the relatively frequent presence of ulcers with perforative complications, and pointed out the use of laboratory analysis of the contained fluid, including the test for acidity as has Nichols. They found that in 2 of 9 cases reviewed there were other developmental abnormalities which were factors in the cause of death. Poncher and Millies called attention to the frequent association of mediastinal enterogenous cysts with abdominal cysts and the presence of marked abdominal symptoms such as pain and tarry stools. In the case of Black and Benjamin the cyst extended through the diaphragm, and also of interest in this case was the history of a grandmother who gave birth to 13 children of whom 10 died before the age of 6 months from

"Intestinal trouble." Carlson stated that such endodermal cysts often cause symptoms, complications, or death in early infancy and that many are discovered in poorly nourished, ill infants who may die of complications before surgical interference is possible. The 4 or 5 cases of enteric cyst that he found all occurred in infants and were

PERICARDIAL COELOMIC CYSTS

In 1940 Lambert (115) reported 2 cysts lying on the anterior pericardium which were removed by Berry and cited 4 other cases, some of which were previously thought to be of other origin. Blades later noted that 5 cases of mediastinal cyst from the Barnes Hospital were reclassified into this group and he included them under his classification of anterior mediastinal tumors.

Freedlander and Gebauer suggested that pericardial defects might be produced by failure of fusion of the embryonic transverse septum with the pleuropericardial or pleuroperitoneal membranes. Lambert attributed the origin of pericardial cysts to failure of primitive mesenchymal lacunae which form the pericardium to fuse with others and instead form independent cavities. He described these cysts as being lined by vascular endothelial cells upon loose fibrous tissue containing capillaries and noted that it was difficult to distinguish between mesothelial and endothelial linings. This author further observed that other cysts have characteristics to distinguish them but these cysts do not have such features. The roentgenological picture was given as a rounded defined translucent mass.

ECHINOCOCCAL CYSTS

Heuer and Andrus (98) stated that these parasitic cysts were rare and cited a case of a dumb-bell cyst presenting on the anterior chest wall. Seven cysts of the hourglass type in the posterior mediastinum were mentioned by them. The finding of scolices and daughter cysts, if perforation occurred, was diagnostic. Signs of spinal cord compression occurred, as in tumors of this location, and would demand similar management. Fluid levels in cysts perforating into respiratory passages, signs of liver involvement eosinophilia (particularly in a foreigner or traveler) together with such reactions as that of Casoni or any of the indicative precipitation and complement fixation procedures were considered of diagnostic aid in echinococcal cysts. Drainage marsupialization destruction of the lining and excision were used in the management of echinococcal cysts, but drainage alone although occasionally apparently necessary in complicated cases was of little curative value in itself and contamination from the contents must be avoided (44 123).

LYMPHANGIOMAS

Michaelis in 1934 was credited with the only recorded cases in the 10 years prior to 1936. He apparently collected 2 cases and reported 1 in which an attempted excision was impossible and

the patient died later (98 159). Lemon in 1931 mentioned a case of cystic hygroma of the left neck and anterior mediastinum followed to autopsy which consisted of endothelial lined cysts in connective tissue and was poorly demarcated from the surrounding tissue. Eloesser in the same year described a case of Bruns of lymphangioma in the supraclavicular area, extending down internally which was excised. Skinner and Hobbs later reported a lymphangioma in a 7 year old boy with symptoms of 3 years duration which was adherent to the pericardium attached by a pedicle in the mediastinum to the region of the thymus, and poorly defined. In this case there were a few other associated small cysts. The tumor was successfully resected in 2 stages and consisted of multiple endothelial lined cysts filled by fluid or gelatinous material with septae containing fat smooth muscle cholesterol crystals lymphocytes, and blood vessels. Arnheim recently reported 2 cases.

Skinner and Hobbs thought that these tumors were probably congenital due to the isolation of somewhat mature cells and that perhaps hygroma of the neck descended with the pericardium from the region of the branchial clefts, although the possibility of thymic origin was considered. Lambert considered lymphangiomas as congenital maldevelopments of the lymphatic vessels and as being composed of loose fibrous tissue lined by mesothelium (which cannot be differentiated from endothelium microscopically). He stated that they were intimately adherent to the adjacent structures and have a profuse blood supply. He was of the opinion that they could occur anywhere. Heuer and Andrus (98) stated that these tumors were found near the hilum or in connection with the pericardium. Blades and Clagett (37) classified them as anterior mediastinal tumors. Carlson expressed the opinion that the onset of symptoms of mediastinal tumor in lymphangiomas occurred somewhat earlier than in such tumors as dermoids and teratomas.

HEMANGIOMAS

Adams and Block recently reported a hemangioma of the mediastinum in a man 34 years of age. The mass was found on roentgenological examination after a cough persisted following respiratory infection. The roentgenological findings were described as several rounded shadows in an opaque density which was less penetrable at the periphery. There was a history of a earlier removal of masses from the left side of the neck and there was an irregular movable mass presenting in the left side of the neck which revealed the

characteristics of hemangioma on biopsy. A soft mass was found attached to the mediastinum at operation and it was necessary to leave a portion anteriorly. There was a somewhat stormy post-operative course with laryngeal cord paralysis but the patient recovered. There was no follow up recorded in the account. A thin capsule was noted on the mass which showed fibrous trabeculae, and cavernous and calcified areas on examination. There were many endothelial lined sinuses containing blood with scattered areas of areolar tissue infiltrated with lymphocytes, and bone with marrow was noted. The authors were able to discover only 1 other case, which was that of a malignant hemangioendothelioma in a man. In that case the tumor was removed but the man died of extension and metastasis.

Hosoi and Stewart described a case of malignant endothelioma, probably of vascular origin seen at autopsy. The tumor was located in the posterior mediastinum behind the trachea and was about the size of a lemon. The tumor was encapsulated and was featured by numerous capillary channels with tumor cells arranged in a perithelial manner around them. No metastasis was noted although the symptoms had existed 1½ years. The authors cited another case of hemangioendothelioma situated in the anterior mediastinum.

Clagett and Hausmann (37) classified benign hemangiomas as anterior mediastinal tumors.

FIBROMAS

Heuer and Andrus (98) were able to find 32 cases of fibromas in this region, in some of which sarcomatous changes may have occurred. Blades (18) was not certain of the diagnosis in all of 32 collected cases. Clagett and Hausmann (37) recently reported a huge intrathoracic fibroma, though it was not certain whether the tumor arose from the mediastinum. Harrington's (76-81) previous reports were of interest, particularly the presence of a bloody pleural effusion with a benign intrathoracic fibroma in one case.

Clagett and Hausmann cited the opinion of Tudor Edwards that fibromas frequently originate from tissues other than the pleura which may be pushed ahead of the growth. Heuer and Andrus (11-98) stated that these tumors may arise from the pericardium, vertebrae, or sternum, and noted 1 on the arch of the aorta. They described the tumors as hard, firm, of varying size adherent, and as occurring for the most part in the anterior mediastinum, although an occasional fibroma was found in the posterior division. In most of the cases other connective tissue elements were found

to be present. Clagett and Hausmann closed fibromas as benign tumors of the posterior mediastinum. In their case the tumor consisted of mature fibroblasts and collagen. They mentioned the danger of confusion with neurofibrosarcoma and it was their belief that fibromas were more apt to undergo sarcomatous change than tumors of nerves.

The symptoms were noted by Heuer and Andrus (98) as appearing late, usually after the age of 40, and with a duration of from a few months to 15 years. The symptoms were found to be much those of mediastinal compression, including venous engorgement. The authors remarked about the clinical silence of such tumors.

These authors considered the prognosis as good with surgery but otherwise hopeless. In their collection of 32 cases, 13 of 14 patients subjected to operation recovered and 1 died, while all of the 18 unoperated patients died. Clagett and Hausmann felt that thoracotomy was indicated for benign lesions not only because of the possibility of malignancy but because the lesions, irrespective of size, may jeopardize the patient by interference with the function of the intrathoracic organs and the risk of later extirpation may be increased. They emphasized the marked physiological change gradually compensated for during the growth of large tumors and the severe disturbance on sudden removal of the mass. This was illustrated by the postoperative hypotension in their case, due to the release of pressure on the vascular system.

FIBROLEIOMYOMA, FIBROMYXOMA, MYXOMA

Heuer and Andrus (98) mentioned this group of tumors in their discussion of mediastinal tumors. The 2 cases of fibroleiomyoma of Jacobson and Einar Key that were situated in the posterior mediastinum and cast a circumscribed shadow on the x-ray film were cited. The tumors were attached to the vertebrae and ribs (periosteum) and were successfully removed. The masses were edematous and smooth muscle was present. The benign encapsulated pure myxoma of Graham (68) was mentioned; this was situated in the anterior mediastinum, was attached to the pleura, presented in the right chest wall, and was successfully removed. Also Heuer and Andrus described their case of myxoma in a 41 year old patient located in the posterior mediastinum and filling the hemithorax, which was successfully removed. Lemon mentioned a case of intrathoracic myxoma and observed that these tumors were characterized by widely separated cells in a mucinous matrix.

LIPOMAS

Fathergil in 1783 was credited by McCorkle *et al* with the first case described. These authors added the reports, since Heuer's (95) earlier paper up to 1940 and collected a total of 34 intrathoracic lipomas. In the monograph of Heuer and Andrus (98) 42 cases were reviewed and all but 1 or 2 were in the mediastinum. Walker discussed the subject and recently Watson and Urban described a huge mediastinal lipoma which was removed. Blades stated that only 2 were found at the Barnes Hospital.

Heuer and Andrus (98) found that it was difficult to determine the origin of these tumors and thought that many were congenital. The tumors apparently vary in character from a pure type some contain fetal fat tissue capillary sinuses, monocytes, and many are made up of lobules as noted in the table of Yater and Lyddane. Heuer and Andrus divided the tumors into those protruding through the chest wall of which they found 13 cases with the patients ages ranging from 6 months to 60 years tumors in the superior mediastinum extending into the neck of which type 5 cases were found and the intrathoracic type majority of these were noted. They noted that the tumors may attain a great size.

These writers observed that the symptoms were the usual ones of a mediastinal mass with palpable tumors noted in the first and second groups. They noted that a long duration of symptoms, when present such as dyspnea from 12 to 20 years, was indicative of early slow growth. McCorkle *et al* found that among 34 cases, 14 of the tumors were palpable, cardiac symptoms were present in 3 cases and that 5 cases were asymptomatic.

Heuer and Andrus stated that a characteristic of lipomas was a decreased density near the periphery of the tumor on roentgenological examination. McCorkle *et al* noted that lipomas were most often mistaken for fluid in the x ray film but pointed out that on aspiration the sensation was buttery or boggy.

Walker stressed the difficulties of removal although the tumor was easily shelled. He noted that bleeding was troublesome because of the subatmospheric pressure after the chest wall was closed and that the physiological changes were rapid, whereas a previous gradual accommodation had occurred with the growth of the tumor. He suggested tight closure of the chest with gradual aspiration as a means of gradual decompression or the removal in stages of large tumors. Watson and Urban thought that removal was in

dicated for these tumors apparently because of the symptoms produced. They placed the patient with his good side down to avoid a rapid mediastinal shift during the postoperative period. Andrus (8) discussed a recurrent lipoma of massive size recorded in the chest tumor registry which could have been removed again.

The results in 13 cases of hourglass tumor were given by Heuer and Andrus (98) as follows in 1 case the tumor was found at autopsy and in 12 cases the patients were operated on the whole tumor being removed in 9 with cure in 7. Among 5 cases of the superior mediastinal type there was 1 case in which the tumor was found at autopsy and 1 in which the patient died despite x ray therapy and 3 cases in which the patients were operated on successfully. In 24 cases of intrathoracic tumor 16 of the patients died untreated (found at autopsy) and 8 were operated on, with recovery in 5 and death in 3. It was pointed out that most of the entire collection were old cases that were operated on before the advent of aseptic surgery.

XANTHOMAS

Phillips in 1937 was able to collect 5 cases of intrathoracic xanthomatous new growth, including 2 of his own and stated that some of the growths were in the mediastinum. Heuer and Andrus (98) in 1940 collected 10 including 1 of their own all of the growths were successfully removed with no mortality. Phillips described these tumors as characterized by the presence of doubly refractile lipid material or a pigment of doubly being of a yellow color. He thought these tumors were apparently of fatty or reticuloendothelial origin but noted that the origin was unknown. He stated that such neoplasms usually arose in tendon sheaths, and those in the chest were located in the costovertebral gutter as a rule but unlike such tumors in other regions those in the thorax were encapsulated—and therefore easily freed. The microscopic picture was described as consisting of doubly refractile lipid (or fatty acid) globules in large polyhedral and small spindle shaped cells with the central cells more distended. He considered xanthomas as apparently non-malignant and believed the term sarcoma should be dropped. Heuer and Andrus (98) noted that in all cases reviewed the ages were between 21 and 50. They observed that the symptoms were the usual ones of mediastinal compression.

OSTEOCHONDROMAS CHONDROMAS CHONDROMYXOMAS CHONDROSARCOMAS

Heuer and Andrus (98) observed 4 such tumors and found 14 in the literature between 1926 and

1940 Harrington (86) reported 1 chondrosteosarcomas in a group of 35 posterior mediastinal tumors. Other reports of interest are those of Heuer (94) Harrington (77) Lemon (117) Graham, Singer and Ballon (68).

Heuer and Andrus (11 98) stated that such tumors were derived from cartilage of the bony thorax and they encroached upon the mediastinum. Lemon believed that they may also arise from the tracheobronchial tree during body development. Harper considered that the origin was uncertain but noted the possibility from fetal rests, from rachitic islands of cartilages, and as a result of trauma. He suggested that osteochondromas apparently arose from tendinous attachments and chondromas from joint cartilage. Blades found that chondromas, although rare, most commonly arose from costal cartilage and occurred in the anterior mediastinum while the others were more common in the posterior mediastinum.

Heuer and Andrus (11 98) described chondromas as solid and cartilaginous while chondromyxomas were considered as partly solid and cystic, containing fluid or gelatinous material. These tumors were noted to be circumscribed, nodular and encapsulated. They crowd but do not usually invade or become adherent to the mediastinal structures. These writers observed that the tendency to recur or metastasize although the tumors were benign microscopically was present as elsewhere. Harper described osteochondromas as exostosis which arose as bony tumors with cartilaginous caps. He described chondromas as containing adult cartilage primarily which may ossify or undergo myxomatous degeneration. He also stated that chondromas were prone to recur and become malignant.

Heuer and Andrus (11 98) further observed that these tumors may become very large and that symptoms occurred in adult life, as growth was slow. The symptoms were those of mediastinal compression with pain usually occurring first, and hourglass types of the spine were noted with signs of cord involvement. Deformity of the thoracic cage may be produced and in the majority of cases of tumor of rib, sternum, or clavicle, the tumor is obvious with pain, swelling palpable mass, and physical signs suggesting its presence according to the authors (98 99). The tumors were usually well circumscribed on roentgenological examination and connection with the bones was suggestive. Such tumors were considered as apparently not amenable to x ray therapy. Because of the tendency toward recurrence and malignancy Harper preferred early removal.

Heuer and Andrus (98) stated that the tumors were easily freed but their size made removal difficult. The results of operative treatment in their 4 cases were apparently successful in 2; there was 1 operative death, and 1 case developed metastases in a year. In the 14 collected cases, 7 patients were operated on with 5 recoveries and 2 deaths in the 7 others the tumors were found at autopsy.

SARCOMAS

Heuer and Andrus (98) stated that the primary sarcomas arose for the most part from connective tissue or benign tumors of the same origin as described before. There were 7 sarcomas among 143 mediastinal tumors in the New York Hospital series, of which 3 were malignant degeneration of benign tumors, 2 were liposarcomas, and 1 came from the subclavian artery. These authors were able to collect 32 cases between 1906 and 1920, of which 17 were classed as fibrosarcomas or fibroblastomas, 13 as sarcomas, 1 as hemangiosarcoma, and 1 as liporhabdomyosarcoma. Cases of interest were described by Eggers (49) and by Harrington (77 79 81). Blades stated that many believe that a high proportion of intrathoracic sarcomas begin as benign chondromas or neurofibromas.

Heuer and Andrus (98) found that these sarcomas usually occurred apically and in both the anterior and posterior mediastinum with encroachment on the contents, but they may arise arising in nerves, develop into hemorrhagic tumors. They stated that the symptoms were those of compression or involvement of the mediastinal structures and the symptoms were progressive with pain, although less rapidly so than those of some malignant conditions. It was the authors opinion that the masses were well demarcated and rounded on the x-ray film as also observed in benign tumors. The presence of metastases suggested the condition and aspiration biopsy was suggested to aid diagnosis.

Andrus (8) observed that sarcomas were particularly fatal. Of the 32 cases collected by Heuer and Andrus (98) there were 19 in which operation was carried out with the removal of the tumor in 18 with 10 recoveries and 8 deaths the late results were not stated. However in 7 cases of fibrosarcoma in which the tumor was removed with recovery there were 3 deaths in 6 months.

Secondary or metastatic sarcomas of the mediastinum is rare and usually seated in the lungs (95).

CARCINOMAS

Adams observed that almost all carcinomas were due to metastasis to the mediastinal glands.

or direct extension from primary lesions of the esophagus or bronchial tree. Blades stated that the thymus was the most common source of primary carcinoma of the mediastinum although often the source of the tumor could not be determined, and the most frequent secondary invader was the bronchogenic variety. Heuer and Andrus (98) also considered that carcinomas arose primarily from the thymus, as described and secondarily from carcinoma of the lung or tracheobronchial tree, esophagus, breast or metastasis from elsewhere. Also they noted that primary carcinoma was less frequent than sarcoma. They stated that the symptomatology and progress in carcinoma were like those in sarcoma, but that carcinoma was not so prone to compression symptoms, which were usually of secondary importance to the symptoms of a primary lesion elsewhere in the case of metastasis. The picture of a Pancoast tumor may be present. Harrington (81) described a case of adenocarcinoma of an intrathoracic goiter and mentioned 2 cases of metastatic carcinoma which could not be distinguished preoperatively (77).

TUBERCULOMA

Grace reported a case of tuberculoma of the mediastinum which he believed to be the only one of the mediastinum recorded. He recognized the question of the classification by stating that the mass was composed of unusual tissue formation in response to the tubercle bacillus, but considered that tumor formations may result from certain chronic inflammatory or other process. He distinguished this condition from tuberculous adenitis and mediastinitis and stated that the difficulty was in differentiating the type of process present before operation is performed. The patient, after a long involved history presented himself with complaints of pain, dyspnea, cough and a low grade, elevated temperature. The tuberculin test was positive and an orange sized, sharply demarcated mass under the arch of the aorta was noted in the left hilar area on the roentgenogram. The mass failed to respond to roentgen therapy and the patient was operated on with the finding of a mass adherent to the pericardium above the lung root.

There was marked relief of the symptoms following excision. There was a thick capsule which contained cream cheese," and microscopically there appeared to be remnants of lymph gland structure with central necrosis surrounded by fibroblastic tissue infiltrated with inflammatory cells suggestive of epithelioid reaction but no definite tubercles.

HOURLASS TUMORS OF THE SPINE

This group of tumors in the mediastinum was described by Heuer and Andrus (98) as tumors of various types arising from tissues intraspinally from the vertebrae and from paravertebral tissues with extension into the intervertebral foramina or between the lamina. The foramina were usually enlarged, apparently in most instances from pressure atrophy rather than from destructive invasion according to Heuer (93). He also found that both the intraspinal and paravertebral portions were, as a rule well encapsulated and separable. Apparently many were of neurogenic origin. Heuer and Andrus (98) noted that the majority appeared to be benign although some were malignant, and some echinococcal cysts were also observed to be of this configuration. According to these writers the symptoms were predominately those of involvement of the spinal cord—of extramedullary spinal cord tumor. Thoracic signs were usually late even in large types. Apparently some of the tumors may present externally (93). Surgical treatment was primarily concerned with the tumor portions compressing the cord and they usually were approached through a laminectomy. The paravertebral portions could also be removed at the same time as a rule by resection of the transverse processes and extrapleural dissection (93). Harrington (86) preferred a one stage combined mediastinotomy and laminectomy unless there was danger of leaving a portion of the tumor.

PANCOAST TUMORS AND OTHER TYPES

Pancoast described a type of tumor characterized by the clinical phenomena of pain in the eighth cervical and upper two thoracic nerve trunk distributions with wasting of the muscles of the hand. Horner's syndrome, defined roentgenological shadow in the apex of the pulmonary sulcus, and destruction of the posterior aspects of one or all of the upper 3 ribs with adjacent transverse processes and sometimes of the vertebral bodies. He considered the tumors thus characterized as of epithelial origin although the exact origin was not definitely determined. Ray apparently showed that various types of tumors of several origins may produce such a picture, of which mediastinal tumors may be the basis, although bronchogenic carcinoma was probably more frequent. He pointed out the degree of inoperability and poor results from surgical treatment in malignant tumors of this type. Heuer and Andrus (98) also stressed that the picture may be caused by even small tumors, pressing on the structures in the region of the sulcus.

Pulsating tumors of the anterior mediastinum were discussed by Horsley who stated that they erode through the sternum by transmitted aortic pulsations. He considered that the most common pulsating mass in the sternum was aneurysm of the aorta. He noted the occurrence of aneurysm of the internal mammary artery plus bone aneurysm as well as sarcoma of the sternum. The observations of Crile, that the majority were malignant and metastatic from adenocarcinoma of the kidney or malignant adenoma of the thyroid were cited. Horsley considered his case as similar to the type Pancoast described, that is, of epithelial origin, and speculated on an origin from a branchial groove rest.

MEDIASTINAL GOITERS

Clute and Lawrence credited A. Haller in 1749 with first anatomically describing intrathoracic goiter. These authors stated that if substernal, "retrosternal" and "subclavicular" goiters are included under the term intrathoracic, from 12 to 30 per cent of all goiters would be so classified but if intrathoracic is applied to only those goiters extending down to or below the arch of the aorta, the incidence is less than from 1 to 10 per cent of all goiters operated upon. They thought that low cervical goiter should not be included under the term. They further believed that goiter arising from ectopic thyroid tissue in the mediastinum was rare. Wakeley and Mulvany found an incidence of 1.34 per cent for partial and 0.23 per cent for total intrathoracic goiter and suggested that the term "intrathoracic" be reserved for those goiters in which the majority or all of the swelling was within the thorax. They also cited Kocher's definition—a portion of swelling remained permanently retrosternal.

According to Clute and Lawrence, the present day experience is that "the thyroid gland in typical exophthalmic goiter rarely if ever extends deeply into the thorax." They stated that intrathoracic goiters were from a single adenoma or more frequently from nodules of multiple adenomatous goiter which descended into the thorax. It was considered that the nodules were usually located at the lower poles or inferior portion of the thyroid isthmus and, because the rate of growth was slow the descent was slow. Growth in the line of least resistance (toward the loose areolar tissue inferiorly) action of the overlying muscles, movements of respiration and swallowing together with gravity were given as the factors aiding descent. These writers found that hyperplasia often occurred with the picture of toxic adenomatous goiter and that there may be degenerative

changes with necrosis, hemorrhage, cyst formation which may enlarge, and calcification. There may be malignant degeneration varying from the localized to the diffuse invading type, or any type of thyroid malignancy may be present. Wakeley and Mulvany agreed that the goiters were usually of the nodular cystic variety and as to the mode of descent. They found them usually to be the seat of degenerative processes, and thought there was an incidence of from 2 to 3 per cent malignant change. Mora Imasaka, and Spencer re-emphasized that practically all cases of intrathoracic goiter were of the adenomatous variety and that Lahey as never having seen a diffuse exophthalmic goiter in the thorax.

Clute and Lawrence observed that the mass may be found on the front, back, or either side of the trachea. They stated that, although it was unusual, goiters did occur behind the trachea as they grew back between the branches of the thyroïd artery and descended there. The blood supply was noted to be the same as for the remainder of the gland. Intrathoracic goiter arising from ectopic thyroid tissue, on the basis of embryology should be in relationship to the aortic arch or tracheal bifurcation and may be connected with the thyroid gland by a fibrous band, according to the authors. They found that in most cases the recurrent laryngeal nerve was pushed backward, although it may be anterior at times in a case posterior to the trachea. Paralysis of the nerve may occur in both benign and malignant conditions, but was rarely found in intrathoracic goiter.

Wakeley and Mulvany observed that the usual signs and symptoms of hyperthyroidism were frequently present but believed that the toxicity was of the milder type and might be overshadowed by the effects of mediastinal pressure. They noted that exophthalmos, loss of weight, and thirst were less apparent, and that the average basal metabolic rate was plus 30. There was evidence of toxicity in 7 of their 20 collected cases. These writers stated that the mediastinal pressure effects were first noted on the respiratory mechanism, then on the esophagus, and finally on the venous return. The majority of these goiters occurred in middle aged women, in their experience. Clute and Lawrence also said that there may be changes from hyperthyroidism, from the presence of a mediastinal mass, and from invasion of the organs by malignant growth. The trachea was first to show signs and effects of pressure, which occasionally could be observed by tracheoscopy. Intrathoracic goiters frequently disappear or not in the neck on cough, or the lower pole on one side of adenomatous goiters may be difficult to

palpate. Movement of the mass up and down with deglutition on fluoroscopy as well as the use of barium visualization of the esophagus, and other roentgenological study (with a well defined high anterior midline, wedge shaped mass 151) were mentioned as suggestive aids in diagnosis by the authors.

Early operation facilitated the removal of such goiters in the opinion of Clute and Lawrence and they thought that this could be carried out with out enlarging the thorax cutting the sternum, or separating the sternoclavicular joint. The usual incision was made and the strap muscles were divided as indicated. A finger was swept behind the capsule of the substernal mass and the veins to the intrathoracic mass were lifted up and ligated at times the superior thyroid artery was also ligated at this point for better mobilization. If the mass could be displaced forward the inferior thyroid artery was ligated, otherwise this was deferred until the mass was delivered. The authors stressed the necessity of staying in the right plane of cleavage to avoid bleeding and entering the pleura. After delivery of the mass, gauze was packed in the defect for hemostasis and to avoid rapid physiological changes. Then the location of the recurrent laryngeal nerve and the parathyroid glands was checked if present they were left behind, and the mass was dissected from the trachea. Drainage was carried out for a few days to prevent fluid accumulation. It was usually found that it was unnecessary to decompress the mass by rupturing the capsule in order to remove it. Mora, Isaacs, and Spencer collected 6 cases, plus their own of posterior mediastinal goiter. They stated that such a goiter could be removed as other intrathoracic goiters, without disturbing the bony thorax. The complications were listed by Wakeley and Mulvaney as hemorrhage, collapse of the trachea, infection, tracheal fistula, laryngeal nerve paralysis, and crisis. There were no deaths in their series. Apparently preoperative and postoperative care is the same as for other thyroid surgery of similar nature.

MEDIASTINAL PARATHYROID ADENOMAS

The clinical diagnosis of hyperparathyroidism was discussed by Lahey and Haggart. They distinguished the osteitis fibrosa cystica of von Recklinghausen from the osteitis of Paget by the presence of large cysts, generalized skeletal involvement, and hyperparathyroidism with adenoma in the former but with only mild hyperparathyroidism occasionally in a parosis form in the latter. A clinical osteitis fibrosa cystica with diffuse granular osteoporosis and multiple cysts,

hyperparathyroidism with osteoporosis as an earlier stage, and a renal type due to precipitation of calcium phosphate in the kidney (in which type there may be no abnormal skeletal picture) were differentiated as classes by them. It was believed that the renal picture indicated the severity and the bony picture the duration of the condition. According to these authorities the disease was predominant in females from the ages of 30 to 50 and the onset was usually with pain in the back or extremities. The disease was characterized by arthritic pains which were worse on motion and the presence of pathological fractures in some. They noted that where cysts were formed there was expansion of the bony cortex with no periosteal proliferation. Subperiosteal rarefactions and small cysts were best seen at the metaphyses of the long bones or margins of the ribs. Kyphosis and crushing of the vertebrae were also observed on roentgenological examination. These writers commented on the diagnostic significance of the elevated calcium and low phosphorus blood levels with increased phosphatase activity as well as the increased ratio of calcium in the urine.

The following discussion was abstracted from the article of Cope

At the Massachusetts General Hospital there were 60 cases of hyperparathyroidism 54 cases of adenoma and 6 cases of hyperplasia of the parathyroid gland. In 4 cases there were 2 adenomas in each case and this was possibly true of 2 others. Eleven adenomas were found in the anterior mediastinum and 5 were noted in the posterior division, with the remainder in the neck. In the 6 cases with hyperplasias, there were 23 glands in the neck and only 1 gland in the posterior mediastinum. After excluding the cases explored previously by others, there was an incidence of 18 per cent of the glands discovered in the mediastinum 10 per cent anteriorly and 8 per cent posteriorly.

Cope believed that parathyroid glands occurred in the mediastinum following embryologic descent. He encountered them from above the superior pole of the thyroid gland to the level of the pericardium. It was stated that the upper parathyroid glands arose from the fourth branchial cleft in relation to a thyroid portion and descended with it. They usually were found above the main inferior thyroid artery but occasionally they were noted anterior to the superior thyroid artery above the thyroid and were usually easier to locate than the inferior glands. The lower glands were considered as arising in the third branchial cleft near the thymus, descending with it laterally to the thyroid gland, and dropping off opposite the

lower pole of the thyroid gland. Some, however descend on down with the thymus to a position low in the neck or to the mediastinum, or they remain in the thymic capsule others may go behind the innominate vein but anterior to the arteries, or occasionally lateral to the aorta. Cope also thought that enlarged glands could be displaced into the mediastinum by their weight, by the negative intrathoracic pressure, or by muscle action. It was considered embryologically impossible for the glands to develop into the posterior mediastinum. It was pointed out that those found there had vascular pedicles leading to the thyroid vessels and that parathyroid glands receive their blood supply from the artery nearest to the place where they are deposited, and are held in place by their vascular pedicle.

Cope thought that the treatment of hyperparathyroidism was surgical, that roentgen therapy was of no benefit, and that dietetic therapy was injurious to the kidneys and bone. He stressed the difficulty in locating the tumor (not usually visualized on the roentgenogram) the special training necessary to recognize the diseased tissue, and bloodless surgery as bleeding confuses the picture. At the first stage, exploration of the neck and posterior mediastinum was carried out through a transverse collar incision with division of the strap muscles and elevation of the lateral thyroid lobe. The upper parathyroid glands were looked for first and, if necessary the search was carried up to the upper border of the larynx or even to the carotid sheath. Inspection was also made behind and in front of the esophagus next the dissection was extended into the posterior mediastinum, avoiding the thoracic duct, and also into the anterior division as far as visible. Aid was obtained by the finding of a vascular pedicle leading away from the thyroid arteries. The capsule of the upper thymus and the sulcus of the thyroid capsule were observed closely. If all the offending glands were not located, the anterior mediastinum was explored at a second stage through a longitudinal incision with a trapdoor division of the sternum down to the level of the third interspace. Search was made from the neck to the pericardium as well as on both sides of the aorta. It was found that the region of the thymic capsule was the most likely location for normal or abnormal glands.

This authority stated that there were many variations of the normal parathyroid glands, but that they were usually soft, surrounded by a thin capsule, and covered with a network of fine vessels leading to a vascular hilus. The glands were molded into the shape of the compressing struc-

ture but were globular when free in fat or the thymus, and their color depended on the amount of contained fat, which increased to the age of 40 and then decreased. Cope believed that in the presence of an active tumor there was an atrophy of disease in the normal gland cells with a relative increase in fat. Both adenomatous and hyperplastic glands were considered as containing little fat and thus they were browner than normal, while hyperplastic glands were possibly darker and more uneven. The size of an adenoma was noted to be proportional to the elevation of the blood calcium and the depression of the phosphorus readings. With a level of 15 mgm. of calcium the tumor was usually large enough to palpate. If an adenoma was smaller than expected on this basis, Cope suggested looking for another. It was mentioned that the surest way not to overlook another abnormal gland was to isolate all 4, as 80 per cent were symmetrical, although the possibility of supernumerary glands must be remembered. Apparently the finding of 1 normal gland excluded hyperplasia in this author's experience and if a gland were larger than expected the possibility of hyperplasia was to be considered. He suggested the partial removal of the gland for biopsy if in doubt. Subtotal resection was recommended for primary hyperplasia and occasionally for adenoma (but not if carcinoma were present). If for example other glands had been removed previously or if postoperative tetany were anticipated, as in extensive bone disease, he also advised subtotal resection, as there may be rapid absorption of calcium by bone. The latter may be predicted by a preoperative phosphatase level of 10 Bodansky units or more. It was noted that the postoperative phosphorus level was lower in this type of tetany in contrast to the hypoparathyroid types, while the phosphatase level was higher, and it sometimes took nearly a year for these levels to become normal. Cope observed that in the literature no hyperfunction was noted in the cases of carcinoma.

In the discussion of Cope's paper Lacey mentioned some successful experience with the transplantation of parathyroid glands. Freedlander stated that in 10 per cent of the cases of hyperparathyroidism, the tumor was located in the posterior mediastinum.

H. B. Alexander, J. de J. Pemberton, E. J. Kipper and A. C. Broders recently discussed the clinical and pathological considerations of functional parathyroid tumors and hyperparathyroidism in the *American Journal of Surgery* of August, 1944. They studied 14 cases of hyperparathyroidism due to the formation of tumor in the parathyroid

glands. It was noted that 4 parathyroid tumors were in the mediastinum (28.6%) of which 3 were located in the posterior mediastinum and 1 of 2 of the tumors were visible on roentgenological examination. These writers observed that in 13 of the 14 cases, the tumor showed evidence of malignancy. They found no correlation between the weight of the tumor and the degree of hyperparathyroidism as measured by the concentration of the calcium in the blood before operation. The results of operative treatment were considered excellent in 12 cases of the series while in 2 cases there was a fatal termination.

E. H. Norris recently reported a study of 322 collected cases of parathyroid adenoma in SURGERY GYNECOLOGY AND OBSTETRICS (INTERNATIONAL ABSTRACTS OF SURGERY 1947 84 1). He found that these tumors originated at practically any time in life with the maximum incidence being in the fifth decade. He also observed that the tumors occurred more frequently in females than in males. This writer concluded that in the majority of cases, parathyroid adenoma is a single nodule involving only 1 gland. He noted that adenomas were found in an aberrant position in 10.7 per cent of the cases of which group 63.3 per cent were located in the mediastinum. The author also observed that only a few patients have symptoms for less than 2 years and that the average duration of symptoms was probably from 5 to 7 years prior to the diagnosis of the adenoma.

EAR

Conley J J: Atresia of the External Auditory Canal Occurring in Military Service: A Report on the Correction of the Condition in 10 Cases. *Arch. Otol.* Chic., 1946, 43: 613

Until the advent of the war atresia of the external auditory meatus resulting from wounds about the ear was strikingly uncommon. In atresia secondary to tumor growth the therapy of the tumor is of first importance.

The author presents 10 cases to illustrate the various types and degrees of atresia secondary to gunshot wounds and other traumas. The cases are divided into four groups, according to the type of the atresia: (1) web type, (2) solid fibrous healed type, (3) solid fibrous and bony healed type, and (4) infected fibrous and bony type.

All subjects were combat soldiers and their average age was 16 years. None had had a previous history of aural disease. Eight of the men had been injured in battle by shrapnel or mortar or machine gun fire, 1 had sustained a fracture of the skull in falling from a truck, and another had been injured in an airplane accident. The points of entrance of the missiles varied from the immediate area of the ear to the middle and posterior portions of the neck, and from a point posterior to the pinna to one anteriorly located in the region of the cheek. In 4 patients there was mild to moderate deformity of the pinna. Eight patients were standing and 2 were prone at the time of injury. Right and left ears were involved in equal numbers. Atresia was complete in all but the 2 infected canals, where fistulas, granulation tissue and pus were present in the scarred mass.

The author's method of treatment of the various types of atresia is as follows:

1. Web type. Corrective measures in the simple, uncomplicated type are accomplished by excising the web and adjacent scar tissue through the endaural approach and implanting a thin, split, free skin graft over the denuded areas.

2. Solid fibrous healed type. Patients with this type of atresia were treated similarly but more extensively. When the newly created flap was not ample, the skin and periosteum were reflected inward the tunnel was enlarged by removing some of the bone on the inferior posterior and superior walls of the canal and then the tissue was replaced in its new bed.

3. Solid fibrous and bony healed type. In this group there was the added factor of fractured bones. The wounds were deeper there was more scarring and considerably more damage to the surrounding structures. In the treatment of these cases radical mastoidectomy was frequently necessary and it was always necessary to do some bone work.

4. Infected fibrous and bony type. Treatment of this type of atresia was essentially the same as in the previous group except that suppuration was present. These cases practically always require a radical

mastoidectomy and chemotherapy and both should always be employed to prevent complications. *JOHN F. DUNN, M.D.*

Gresley P W: Reconstructive Otoplasty: Further Observations: Utilization of Testalium Wire Mesh Support. *Arch. Surg.*, 1946, 53: 14.

The reproduction of an auricular cartilage still remains the greatest problem in the construction of a new ear. In an earlier paper personal experience with Gillies' method utilizing a maternal or orifice as the architectural support around which to build a new ear was described in detail. Subsequently a total of 15 ears were constructed by this procedure.

At first, it appeared that the method, as originally presented by Gillies, was a great step in the successful performance of this persistently difficult plastic operation. However as time progressed, it became apparent that these transplanted auricular cartilages were not going to remain in their original position permanently. In each case, the individual cartilage underwent aseptic necrosis and was replaced by fibrous tissue. By and large, this transition developed in from 1½ to 2 years in small children and in from 6 months to 1 year in patients of adolescent age. Consequently with the fibrous tissue replacement, the inevitable contracture typical of all scar tissue ensued and the resulting ear shrunk to a small irregular structure. This resulted an ear which was unsatisfactory to both the patient and the surgeon.

Through the co-operation of an engineer wire models of ear cartilages were constructed of testalium. The author eventually selected a fine wire mesh model, which was not only lighter but would permit development of circulation between the open spaces. These reproductions were made from a model of the normal ear.

A case is presented in which a mold of wire testalium was buried beneath the skin in a patient who had suffered the loss of an ear some months previously. The mold was untouched for 7 months, after which the skin flap was reopened and the posterior surface of the new ear and the temporomastoid bed were covered with a stent graft.

Twenty-five months after operation the mold was still in place without apparent tissue reaction.

NOSE AND SINUSES

Kazanjian, V H., and Holmes, E. M.: Stenosis of the Nasopharynx and Its Correction. *Arch. Otol.* Chic., 1946, 44: 86

An analysis of the literature indicates that congenital atresia of the nasopharynx is rare and that the majority of cases occur following an operative procedure sometimes complicated by sepsis. In a smaller group of postoperative cases there may also be an atresia of the oral pharynx because the tongue is drawn upward into the tonsillar fossa. Infections such as syphilis, tuberculosis, diphtheria, and rheumatism may also produce scarring and stenosis.

Fig. 1 (Kazanlian) a, The complete stenosis of the nasopharynx except for the small perforation. dotted line indicates the initial incision through the mucosa. b, diagrammatic illustration of flap 1 dissected free, leaving one half of the thickness of the tissues to form flap 2 which the dotted line indicates. c, the second flap created and the opening made into the nasopharynx. d flaps 1 and 2 sutured in their final positions covering all raw surfaces and creating a nasopharyngeal opening. e, diagrammatic section to show the stenosis and the dissecting incisions employed to create the flaps. f, flap 1 dissected free. g, flap 2 completed. h, method in which flap 1 was made to come in contact with raw surface of the posterior part of the pharyngeal wall.

Syphilis produced the thickest scarring and the most difficult type to treat. If the patient with syphilis has sufficient opening to care for nasal secretions it is recommended not to disturb the nasopharynx.

The common surgical methods of using a plug in the nasopharynx following removal of scar tissue, or the application of a skin graft to a denuded area has not been satisfactory. Failure has been due to the impossibility of immobilizing a skin graft in the nasopharynx, the poor vascular supply and ever present sepsis. The author describes three methods of creating flaps of the neighboring tissues so that denuded areas resulting from excision or correction of the stenosis are covered by mucous membrane. The advisability of determining the extent of the fibrosis and scarring preoperatively is stressed. This can be done by palpation with a probe through the nose and a finger in the mouth and by nasopharyngoscopic and roentgenographic examinations. In most cases a diaphragm had been created by the scar tissue, which closes off the nasopharynx from the oral pharynx.

Three cases are reported in which hinged flaps of mucosa were prepared and sutured in position after correction of the stenosis so that the denuded sur-

faces were prevented from growing together again. Because the extent of mucosa is likely to be inadequate after correction of the stenosis which allows the tissues to fall back to their normal position a third method was devised in which a pedicled flap from the cheek was swung into position to cover a denuded surface which could not be adequately covered by the hinged flap. The flaps are clearly illustrated by diagrams.

JOHN R. LINDSAY M.D.

Wright, R. W.: Round Shadows in the Maxillary Sinuses. *Laryngoscope*, 1946 56 455

A great many interesting problems arise as to the nature and clinical significance of cystic or polyplike structures in the maxillary sinuses. Among these are the question of their symptomatology, the possibility of their acting as a focus of infection, and the mechanism of their production. These are the questions which the rhinologist would like answered when he examines an x-ray picture showing one or more round shadows in the maxillary sinuses.

Cysts are classified as follows:

1. Benign cysts arising from the jaw or teeth
 - (a) follicular or dentigerous cysts (b) radicular or dental cysts (c) median anterior maxillary cysts

2. Benign cysts arising from the sinus mucosa. (a) secreting cysts, including gland cysts and mucoceles (b) nonsecreting cysts of the sinus mucosa.

The symptomatology of antral cysts is divided into several groups for clarity and convenience: (1) symptoms arising directly from the cyst (2) those arising indirectly from the cyst and (3) cysts producing no symptoms. In the first group there were 9 cases in which the patients had pain and soreness in the face pain in the teeth and (in one) numbness of the upper lip. All of the patients were relieved by puncture of the cyst.

Joint pains vague pains and headache, fatigue, low grade fever and dizziness are other conditions suggesting a focus of infection.

The treatment of cysts of the antrum in civilian life depends upon the symptoms presented. In aviation practice the presence of a cyst is considered evidence of sinus disease and its removal is a necessity for qualification, which accounts for the high percentage of surgical procedures.

In the author's cases many of the asymptomatic cysts were discovered on routine x ray examination of the sinuses.

Seventy-eight cases are presented. Forty-two of the patients were operated upon by means of the Caldwell-Luc technique, and in all but a few of the cases no opening was made in the nose. The pathological structure most frequently found was the non-secreting or mesothelial cyst and in 38 patients the cysts were of this type.

In a summation, the author states that round shadows seen in x rays may represent a cyst or a polyp and positive x ray findings do not represent a definite pathological entity.

JOHN F. DILLON, M.D.

LITTLE, H. I.: Osteomyelitis of the Maxilla Secondary to Suppurative Maxillary Sinusitis. *Ann. Otol. Rhinol.*, 1946 55 495.

The mechanism of the occurrence of osteomyelitis of the maxilla following operations on the maxillary sinus is suggested, as the sequence of symptoms and signs seems to be explained on anatomic and pathological bases.

The pathological characteristics of osteomyelitis of the maxilla that occurs secondarily to suppuration of the maxillary sinus differ greatly from the pathological characteristics of osteomyelitis of the frontal bone that occurs secondarily to suppuration of the frontal sinus largely because of the difference in the character of the bone involved. In the maxilla, because of the difference in the arrangement

It is emphasized that accurate classification of the infecting organism is essential if penicillin is to be an adjuvant in treatment is to be employed effectively. It is also stated that in the presence of penicillin chemotherapy nor penicillin can be relied on as curative agents. The use of chemotherapy and penicillin should be continued for several days following apparent resolution of the infective process.

MOUTH

BERNIER, J. L.: Mixed Tumors of the Lip. *J. Otol. Surg.* 1946, 4 93.

A review of slightly less than 600 mixed tumors of the salivary glands at the Army Institute of Pathology revealed 38 of the lips. Of these, 35 occurred in the upper lip. The greatest number occurred between the ages of 30 and 40 years. The embryologic background of the upper arch is probably a factor in the histogenesis as entrapment of epithelial remnants. The theory of origin on the basis of metaplasia of the epithelial cells of the striated excretory ducts (Stuart, Foote, and Becker) may also account for a number of these tumors. The lesions were extremely variable. Epithelioid tendencies on the part of the epithelial component was striking in some cases, manifesting either a typical basal cell character or squamous features. In some, the epithelium appeared to be of the transitional type. Cartilage or chondroid stroma was present in about one-half of all tumors. A mesenchymatous tendency was evidenced in some by numbers of excretory and striated ducts. No evidence of malignancy was found in any of the group. Most of the tumors were well circumscribed, with a well-developed capsule. The myxoid or chondroid stroma is distinctive of these so called mixed tumors.

JOHN R. LINDSAY, M.D.

SLAUGHTER, D. P.: Multicentric Origin of Intraoral Carcinoma. *Surgery* 1946, 30: 133.

The final outlook in the present day treatment of intraoral cancer is so discouraging that an evaluation of the reasons for therapeutic failure is indicated. Many failures are due to cervical node metastases, but not enough attention has been given to the reason for recurrence at the primary site after adequate treatment has apparently been given. These poor results are universal in spite of recent therapeutic developments.

It is accepted that a malignant tumor is a collection of pre-existing cells which destroy the surrounding tissue. However, does not believe that such a simple view of all the aspects of the growth and

SURGERY OF THE HEAD AND NECK

canalization refers to transformation into cancer of the benign epithelium at the edge of the tumor because of some carcinogenic effect of the cancer cells. This theory is an old one that has been considered as false in the past, but which is again being considered as a possibility in the growth and recurrence of cancer.

spread of intraoral cancer. More studies are needed on this subject before any definite conclusion can be made.
WILLIAM A. ABRAM, M.D.

PHARYNX

McClure G.: Odontoma of the Nasopharynx. *Arch Otolaryng.* 1946 44: 51

A study of 80 cases is given which offers some support to the idea of "multicentric origin and 'lateral cancerization.'" These cases were treated in the last 25 years at the tumor clinics of the Illinois Research and Presbyterian Hospitals. The cases are classified as to the distribution and size of the tumors. Table I shows the distribution, while Table II gives the locations of multiple tumors.

Odontoma of the nasopharynx with a deciduous tooth puts the growth in the classification of osteofibroma of dentigerous origin. The location of the growth was unusual, rare for this type of tumor. Careful search of the literature did not reveal a single case of odontoma of the nasopharynx. The origin of the growth could not be determined but apparently the tumor sprang from the posterior ramus of the mandible. A tumor of this type when situated within the mandible or the maxilla appears to be completely separated from the surrounding bone by its capsule therefore one may assume that it had no attachment. The audiogram revealed a typical conductive hearing loss in the left ear due either to complete obstruction or to absence of the eustachian tube.

In favor of the lateral cancerization theory is the fact that many of the tumors show a greater spread laterally than in depth. Microscopic study of biopsy specimens, and especially of whole tumors which had been surgically removed gives some evidence to support the idea of multicentric origin. Several cases are discussed in more detail and 9 microscopic photographs are included to illustrate the discussion.

Although this is a small series of cases Slaughter states that these three factors—lateral spread multiple tumors, and microscopic evidence of multicentric origin—seem to suggest that more than one mechanism exists which leads to the growth and

The recurrence of the tumor was definitely due to a small portion of the capsule which remained in the extreme lateral part and contained tooth remnants in the bony structure with the power of regrowth. This regrowth is typical of odontoma, the second tooth presenting itself to the surface, in this case the nasopharynx.

The recurrence of the growth and the formation of a second deciduous tooth definitely put the tumor in the classification of a compound composite odontoma.

Magnusson P. and Sørensen G.: The Treatment of Hyperthyroidism with Methylthiouracil. *Acta med. scand.*, 1946 125: 163.

The authors review the literature on the treatment of hyperthyroidism with methylthiouracil with emphasis on (1) the discovery of antithyroid substances (2) the effect of these substances on experimental animals and (3) the effect and by-effect of these substances when employed for therapy in the human being.

A résumé covering the treatment of 46 patients with methylthiouracil is presented. In 3 cases methylthiouracil was used for preoperative treatment. One patient died with a severe degree of thyrotoxicosis. Thirty-eight patients tolerated the methylthiouracil and a normal metabolism was obtained. The suggested dosage is 40 mgm. daily. The maintenance dose is about 10 mgm. every other day but many patients are maintained on a smaller dose. The treatment was discontinued in 10 cases. Three of these patients are still symptom free. 5 have had a relapse. 1 patient died of an intercurrent disease and 1 has not been followed up. The untoward reactions from this treatment were: 1 case of granulocytopenia

14	Tongue anterior and posterolateral

12, 3 cases of drug fever 1 case in which there was drug fever and swelling of the salivary glands 1 case of thrombopenic purpura and granulocytopenia and 1 case of polyneuritis

It is strongly recommended that treatment with methylthiouracil be given only in hospitals where frequent laboratory control examinations may be carried out

RICHARD J. BENNETT JR., M.D.

Parnley, C. C. and Heilwig, C. A.: Lymphadenoid Goiter: Its Differentiation from Chronic Thyroiditis. *Arch. Surg.* 1946, 53, 90

In recent articles lymphadenoid goiter has been recognized as a pathological and clinical entity but its causes, histogenesis and clinical significance are little understood. The author's report is based on 14 cases of this condition.

The clinical findings in the 14 cases were as follows: all 14 cases were in women the average age being 44.7 years. Thirteen complained of enlargement of the thyroid gland 11 had noticed nervousness, and 3 had rapid heart rates. Only 3 of the 14 patients had regular menses. The preoperative diagnosis was nontoxic goiter in 8 cases, fetal adenoma in 2 and toxic goiter in 4 cases.

The pathology of the condition is described in detail. While the abundance of lymphoid tissue is a most conspicuous feature the authors state they found by actual measurement that only one third of the enlargement of the thyroid gland is due to the lymphoid tissue while two-thirds consisted of epithelial tissue.

The thyroid epithelium was of two types: a high cuboid epithelium arranged in small acini, and a large pale polygonal epithelium arranged either in acini or in solid cell strands. The authors regard the latter to be identical with the cells of Hurthle.

The authors believe that the lymphadenoid goiter has lost its ability to manufacture colloid and that this is due to hyperactivity of the hypophysis following loss of ovarian function.

F. J. LEITERMAN, J. M.D.

Auerbach, O.: Laryngeal Tuberculosis. *J. Otolaryng. Chic.*, 1946, 44, 91.

Although there are many studies of laryngeal tuberculosis, most of these are based on clinical observations. The pathogenesis of laryngeal tuberculosis, over which there has been much controversy, should not be studied from clinical findings alone, but cause organs other than the larynx must also be examined. The clinical findings should be combined with pathological studies. In the course of study by Auerbach and his colleagues, the larynx is routinely examined for gross and microscopic pathological changes. An opportunity was thus afforded to study the mode of development and the progression of laryngeal tuberculosis as well as its relationship to tuberculosis occurring in other parts of the body.

Laryngeal tuberculosis was present in 34 (7.1 per cent) cases of tuberculosis which came to autopsy. In all but 2 instances it developed as a direct infection from positive sputum in chronic pulmonary tuberculosis. The age, sex, and race distribution of this series parallel those in chronic pulmonary tuberculosis. Tuberculous foci, with and without central zones of caseation, form in the walls of the larynx as a result of tubercle bacilli which enter through the ducts of the mucous glands. Ulcers develop either through pressure atrophy of the mucous membrane by the tuberculous foci or by caseous necrosis of the overlying epithelium as the tuberculous areas enlarge. The further progression of the ulcerative process is similar to that in other parts of the body. Ulcers were found most frequently on the true vocal cords.

Healing may occur in any stage of anatomic development, usually in cases in which underlying chronic pulmonary tuberculosis undergoes spontaneous healing. In some instances healing and progression keep pace in the same larynx, resulting in pronounced thickening of the wall, nodular protrusions into the lumen, and narrowing of the canal.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Jegel E. A., Spiegel Adolf, M., and Wycis H. T.: Cerebral Concussion; Histochemical Demonstration of Nucleases in the Cerebrospinal Fluid *Arch Path. Chlc.*, 1946, 42 175

By spectrophotometric examination of the cerebrospinal fluid in patients, following concussion, it had been noted previously by these authors that substances were present which were interpreted as nucleic acids or their derivatives. These gradually disappeared as the fluid was allowed to stand and this disappearance was thought to be due to some type of enzymatic action. Cerebrospinal fluid from both normal patients and those who had suffered cerebral concussion was incubated with nucleic acids. The quantity of these acids decreased in the concussion samples but no decrease was noted in the normal fluids or in nucleic acids mixed and incubated with saline solution. This work substantiates the assumption that enzymatic substances acting on nucleic acids or their derivatives appear in the cerebrospinal fluid after cerebral concussion.

Since spectrophotometry is such a specialized technique, a simpler method was sought to investigate this problem. It was decided to utilize the nucleic acids found in the anterior horn cells of the spinal cords of cats. Cerebrospinal fluid was incubated with paraffin sections of spinal cords and this was followed by microscopic examination of the nerve cells with reference to the Nissl bodies.

Preliminary experiments reiterated the importance of the relation between the degree of tigrolysis and the pH. Ringer's solution as well as the cerebrospinal fluids produced tigrolysis when incubated with spinal cord sections. A difference was noted when the pH was lowered. With the pH between 5.0 and 4.1 no effect of Ringer's solution or the cerebrospinal fluids following incubation was significant. With a pH of 4.6 or above, the Nissl bodies became finer. The authors conclude that "at the normal hydrogen ion concentrations of the body fluids or kept in solution and only when postmortem changes cause an accumulation of acids in the central nervous system are the nucleoproteins precipitated and the results are Nissl bodies."

In the final experiments paraffin sections of feline spinal cords fixed in alcohol were used. These were deparaffinized and different sections were incubated with cerebrospinal fluids and Ringer's solution, in phosphate buffer solution of 4.05 pH before incubation at 37° C. for 4 hours. The sections were then washed and stained with thionine solution. The following

1 Sections incubated with cerebrospinal fluid from patients who had undergone cerebral concussion showed tigrolysis of the anterior horn cells.

2 Similar procedures with normal cerebrospinal fluid and Ringer's solution failed to exhibit such an effect.

3 Histochemical findings correlated with spectrophotometric examination of the cerebrospinal fluids those fluids producing tigrolysis decreased the absorption bands characteristic of nucleic acids while those fluids not affecting the anterior horn cells did not result in such spectrophotometry.

The authors hypothesize the significance of enzymes (probably nucleases and deaminases) as the cause of chromatolysis following cerebral concussion.

C. FREDERICK KESTLE, M.D.

Heinbecker P.: Cushing's Syndrome *Ann Surg* 1946, 124 255

Cushing's syndrome is characterized by painful adiposity confined to the face, neck, and trunk; kyphosis of the upper thoracic spine; hypertrichosis of the face, neck and trunk in females and preadolescence in males; dusky plethoric skin with purplish linear atrophicæ on the abdomen and thighs; hypertension; backaches; abdominal pains and weakness; and dryness of the skin with acne and sometimes skin infections. Occasionally there are hyperglycemia, glycosuria, diminished sugar tolerance, polyphagia, and polydipsia.

Cushing was aware that similar clinical findings were found associated with tumors of other glands such as the adrenals but hypothesized that the primary cause was a basophil adenoma of the hypophysis which belief is considered erroneous because basophil adenomas are found without the syndrome and the syndrome is found without an associated basophil adenoma.

The author states that the primary cause of the condition may be a tumor of the adrenal cortex, the ovary or the thymus. In a group of cases without a primary tumor there was atrophy of the paraventricular nuclei of the hypothalamus.

The neural hypophysis of dogs was denervated by separating it from suprapituitary and paraventricular nuclei which resulted in loss of basophilic cells in the glandular hypophysis. A comparison of the histological sections of the other endocrine glands in a dog without basophilic cells with the endocrine glands in a totally hypophysectomized dog show what organs are affected by the eosinophil and basophilic cells. They indicate that the eosinophils are trophic to the adrenals, prostate, interstitial cells of the testis and corpus luteum while the basophils are trophic to the thyroid and ovarian follicle and are essential for germ cell maturation.

Desoxycorticosterone is an antagonist of the hormone of the neural hypophysis. A state of diabetes

insipidus results when it is given to dogs. The author believes that adrenal cortical tumors causing Cushing's syndrome secrete enough desoxycorticosterone to neutralize the hormone of the neural hypophysis and result in degeneration of the basophils. The chemical structural similarity between desoxycorticosterone and progesterone is cited. With that in mind one might expect ovarian tumors secreting a progesteronelike substance to bring about degeneration of the basophils.

DANIEL RUCK, M.D.

Sperling, H. J. Jr., and Adams, R. D.: Primary Hodgkin's Sarcoma of the Brain. *Arch. Path., Chlc.*, 1946, 43, 338.

A case of primary Hodgkin's sarcoma involving the left frontal lobe of the brain is reported.

The patient presented a progressive intracranial lesion of rapid course involving the left hemisphere without evidence of any other neoplasm involving other parts of the body.

At operation, a tumor was resected and microscopic studies revealed a Hodgkin's sarcoma.

The patient succumbed a few days later and it was possible to obtain a complete autopsy. However this failed to reveal any other evidence of tumor involving other portions of the body.

The authors state that this is the only reported case of primary Hodgkin's sarcoma originating in the brain.

HOWARD A. BROWN, M.D.

Kettell, E.: Neurinoma of the Facial Nerve. *Arch. Otol. Chlc.*, 1946, 44, 153.

This article reviews the case history of a 35 year old woman who 7 years previous to operation, suffered a severe pain behind the right ear followed by sudden complete right facial paralysis and gustatory changes. The paralysis cleared up partially under conservative care, but the pain persisted. Once again, the paralysis suddenly became complete, this time without improvement. The condition was diagnosed as relapsing Bell's palsy, and the decompression operation of Ballance and Duell was carried out, during which operation a neurinoma the size of a hazelnut and arising from the descending portion of the facial nerve was discovered. Although there was considerable bone destruction, roentgenograms of the involved bone gave no hint as to the presence of the tumor.

Neurinomas are tumors arising specifically from the cells of the sheath of Schwann, and therefore they are ectodermal in origin. They are probably best known so far as the cranial nerves are concerned in the form of the acoustic neurinoma. They characteristically occur on the sensory roots or in the pure sensory cranial nerves (the olfactory and optic nerves, not being true peripheral nerves, being excepted). They may however occur in mixed motor and sensory nerves, arising from the sensory portion thereof. Several cases of neurinomas forming in the facial nerve are on record, and histologically so proved, and this brings up the question of whether

or not the facial nerve is a pure motor or a mixed nerve. The author apparently is first aware of the fact that the facial nerve is, indeed, a mixed nerve, the presence of the tumor in his patient.

The treatment of these tumors, if they can be diagnosed is strictly surgical, and after they remove the gap in the badly damaged nerve must be repaired with a nerve graft, upon which procedure the author looks with considerable optimism. A point of practical importance is the differential diagnosis between a simple Bell's palsy which also frequently shows relapses and is accompanied by pain, and an intra-neural neurinoma such as the author has described. Perhaps the main point of differentiation between the two conditions, requiring such different treatment, is the continuous pain which is likely to be present when a tumor exists, whereas in Bell's palsy the pain is usually transient.

JOHN MARSH, M.D.

Cairns, H., Guthrie, E. B., and Smith, H. V.: Intrathecal Streptomycin in Meningitis: Clinical Trial in Tuberculous, Coliform, and Other Infections. *Lancet, Lond.*, 1946, 1, 152.

The authors state that supplies of streptomycin are scarce and many medical centers are trying to obtain the drug. This urgency may be somewhat dampened by the report that the results thus far are not nearly as dramatic as are those obtained with penicillin, and that in the use of streptomycin certain special safeguards may be necessary.

Streptomycin was used in cases of meningitis due to organisms shown to be sensitive in vitro and in laboratory animals. Seven patients with meningitis were treated and all but 1 died. There were 1 case of *Pseudomonas pyocyanea*, 1 case of *Haemophilus influenzae*, 3 cases of *Mycobacterium tuberculosis*, and 1 case of *achromobacterium*. The patient with *achromobacterium* infection was the one who survived.

Reactions to intrathecal injection of the drug believed to be due to impurities, were observed in 3 cases. Reaction to injection by the lumbar route was mild in 1 case, severe in 2 cases, and fatal in 1 case. In one of the patients with very severe reaction, streptomycin was given also into the ventricle. The ventricular use of the drug produced a reaction in 1 patient in another with an indwelling catheter no reaction occurred. Streptomycin, compared with penicillin, spreads slowly through the subarachnoid space and the bactericidal effect in vivo is not nearly as great as in vitro experiments would indicate. It is suggested that the acid reaction of pus may account for this.

A dosage of from 80,000 to 100,000 units once or twice daily is probably necessary but in the acutely ill patient this dosage is not free from danger. The ill patient should be given slowly—5,000 to 10,000 units a minute—and a safety valve indwelling ventricular catheter should be employed to keep the intraventricular pressure below 300 mm. of water.

ANDREW VEE BRUCE, M.D.

Hortens W W: Invasion of Paranasal Sinuses by Tumors of Meningeal Origin. *Am. J. Orthodont.*, 1946, 32: 556.

The author presents two case reports of meningiomas infiltrating into the paranasal sinuses. Although the extension of meningiomas through the calvarium is of frequent occurrence their penetration through the base is unusual.

In the first case an olfactory groove meningioma was removed. Three years later the patient was treated for a nasal recurrence. Six years after the left nasal chamber was thought to extend into the sinuses and the left orbit. When last seen 8 years after the initial surgery there was no evidence of further intracranial growth despite extension into the nasal passage. The histopathological diagnosis was meningotheioma.

The second case revealed extension of the neoplasm into the left ethmoid sinus and antrum the tumor filling the left nasal passage when the patient was first seen. The patient expired after an enucleation of the left frontal tumor was found to occupy the left frontal fossa, with extension into the left ethmoid and ethmoid sinuses. Histological study revealed a fibroblastic meningioma with transition into a greater fibroblastic stromal element as the tumor spread to the nasal cavity.

Both tumors were regarded as benign despite their rather extensive spread.

Jack L. Wooler M.D.

SPINAL CORD AND ITS COVERINGS

Diaz, J: Persistent Sciatica Due to Hernia of the Intervertebral Disc; 14 Further Observations (Clínic rebekle por hernia de disco intervertebral. Resultado de 14 de otras catorce observaciones). *Rev. Acad. Argent. Cir.* 1946, 30: 439.

Sixty-one patients with sciatica due to hernia of the intervertebral disc have now been operated upon. Of these the cases of 21 were previously reported during the period from August, 1944 to April, 1945. The remaining cases will be reported later.

Contrast radiography has not been abandoned in these cases. The author admits one instance in which the contrast substance apparently caused a postoperative sciatica however without this method of examination he would never have been certain that there was a hernia of the intervertebral disc and would not have persisted so far in demonstrating its presence. He is still not sorry that he used minimal incision advocated by Love, since the former method permits section of the sensory root, or that there was a hernia of the intervertebral disc. This is always done by the sensory root, or laminated or bears other evidence of being involved in conditions of pressure or irritative inflammation. Laminectomy is also the only method of procedure in the presence of the so-called concealed disc of Dandy. Love's recommendations were made in the

day when it was thought that a laminectomy would require a coincident ankylosing operation for support of the spinal column at the level of operation. However, the author's or patients not one patient was given a fusion or other bracing of the spine, not one had to wear a corset or other support and not a weakness in the spine.

The herniated disc sequester may reduce it self spontaneously during the operation but may usually be demonstrated by placing the patient in the position of exaggerated lordosis on the operating table. The author believes that the condition designated by Dandy as a concealed disc, and ascribed by him to a primary degeneration of the substance of the disc, is in reality this type of self reducing hernia. The section of the sensory root at the level of the disc is in reality this type of self reducing hernia. The section of the sensory root at the level of the disc is in reality this type of self reducing hernia. The section of the sensory root at the level of the disc is in reality this type of self reducing hernia.

In the 14 cases here reported the operation in all but two instances was performed entirely under rachis anesthesia (0.07 gm. of percaine). In the one patient the operation was started and finished under local anesthesia and in the other patient, this method was instituted after the rachis-anesthesia. In all instances, except one, the discal sequester was removed in this case a concealed disc of Dandy was diagnosed and no sequester could be located. Nevertheless even in this patient, with cutting of the sensory fibers of the fifth root the result was immediate definite and excellent, certainly superior to that to be expected from extirpation of the disc by morcellation, as advocated by Dandy. In every case removal of the sequester, and section of the sensory root affected has given uniformly successful results the patient has been up in a few days has returned to work (often heavy work) the pain has not returned, and the strength and mobility of the spine has remained unaffected. In only one instance was there even a partial failure this consisted in the development of a sciatica on the right side a year after the pressure on the left side had been removed.

John W. Breckman M.D.

SYMPATHETIC NERVES

Goodman, E. N. Messinger W. J., and White J. C.: Indications and Results of Surgery of the Autonomic Nervous System in Naval Personnel. *Ann. Surg.*, 1946, 124: 504.

In Naval personnel, surgery of the sympathetic nervous system has been performed for causalgia, pain after amputation, peripheral vascular disease, hyperhidrosis, hypertension and angina pectoris. The authors accept the theory of Doupe, Cullen and Chance. The qualities of causalgic pain are due

to direct cross-stimulation of sensory fibers by afferent sympathetic impulses at the point where the nerve trunk is injured. They have successfully done preganglionic sympathectomies upon patients whose symptoms were relieved by paravertebral procaine block. Among their 13 cases of causalgia there were 7 of the median nerve, 3 of the median and ulnar nerves combined, and 1 each of the ulnar common peroneal, and posterior tibial nerves. Ten patients obtained complete relief, the other 3 retained slight residual aches.

When there is pain in an extremity following amputation of a part of the extremity and this pain is not due to a neuroma or phantom limb, the authors have done sympathectomies when relief was obtained by paravertebral procaine block. Their 6 patients had traumatic amputations of either the fingers or toes. These patients were then bothered with deep aching pains and hyperesthesias. Four obtained complete relief and 2 patients were definitely benefited.

The extremities of patients with peripheral vascular diseases are observed for color and rapidity of color change with position changes, temperature differences, absence of peripheral pulse, oscillometric readings, degree of sweating, and x-ray evidence of arterial calcification. Either peripheral nerve block or paravertebral block are done to study changes in the temperature and color. In Raynaud's disease there are good results in the group that has not progressed to the cold white hand with endarteritic changes; therefore early diagnosis and operation are important. The authors cite 4 cases in which the circulation improved and there was no sensitivity to

cold. They have operated upon 7 patients with thrombo-angiitis obliterans. Five of these had claudication and were relieved of it after operation. Three had ulcers which healed promptly after surgery. All were told not to use tobacco in any form and to use alcohol prophylactically. Sympathectomies were done upon 2 patients who had arteriosclerosis with vasospasm. Both had pain in a lower extremity which decreased following surgery. The authors believe that success will result in only three cases with excessive sympathetic tone. One patient whose popliteal artery was severed by a scapula had to undergo arterial ligation, which left the leg cold and painful. This was relieved by sympathectomy. Two patients with hyperhidrosis were subjected to sympathectomies and warm dry extremities resulted.

Radical bilateral thoracolumbar sympathectomy for hypertension were done on 14 people, mostly between 35 and 55 years of age. Renal function was evaluated by PSP, urea clearance, creatinine tests, frequent urinalysis, and pyelogram. The lability of the blood pressure was studied by cuff pressure tests and sodium amytal sedation tests. Funduscopic examinations were done by competent ophthalmologists. The operation failed to produce a significant lowering of the blood pressure in only 1 case. The authors are very optimistic for the hypertensive patients who have surgery before the age of 50, but admit that they have not followed up their patients very long.

Two patients with angina pectoris not relieved by nitroglycerine were subjected to resection of the upper thoracic ganglia on the side of most severe pain. Both were relieved. DARRY RICE, M.D.

SURGERY OF THE THORAX

TRACHEA LUNGS, AND PLEURA

Abstract II: The Pulmonary Artery Its Ramifications and Relations (Arteria pulmonar Sus ramificaciones. Sus relaciones) *Revista méd. argent* 1946 33 1463

This is an exhaustive anatomical description of the pulmonary artery based on a specimen studied by corrosion, roentgen ray examination, and dissection. The description of the arborization is carried out to the fifth and sixth order. Variations in the manner of branching are pointed out but the standard or common types alone are emphasized in the present article.

The right pulmonary artery is used as the sample artery the author considering the left main trunk to give off the same branches as the right. One standard deviation which he makes note of is the manner of branching of the artery after it branches off to the dorsal segment of the lower lobe. On the left, he considers the artery to end in the lower lobe by bifurcation into anterior and posterior trunks of equal length, whereas on the right the pulmonary artery continues into the lower lobe as such gradually diminishing in caliber as it gives off numerous branches to that lobe.

The points of more practical interest concern the branches given off to supply the various pulmonary segments. The first branch from the right pulmonary artery arises therefrom to supply the upper lobe before the artery actually enters the lung substance. Another separate branch is also almost constantly present to supply the upper lobe. The left upper lobe is supplied by two or three branches. When it is supplied by two branches it is similar in disposition to the right side. When there are three branches they generally follow the main bronchial distribution.

The artery to the middle lobe is again described as a branch from the main trunk. There may be one or two branches arising independently a third smaller branch is sometimes seen, although typically it is a single artery which promptly divides. The lingular branch, according to the author's designation, is a branch from the inferior division of the middle lobe artery.

The branch to the dorsal segment of the lower lobe is typically single but may be double. It usually arises slightly above the middle lobe artery on the left and at this level on the right. The terminal branching to the lower lobe has been described. The manner of branching of all these vessels is given generally in relation to bronchial and venous patterns and the areas of lung substance supplied are keenly well worked up.

Numerous diagrams photographs of the specimen prepared by corrosion, and a roentgenogram of an injected subject are appended for illustration.

HIRSH T. LARSEN M.D.

Leriche, R.: Large Emboli of the Pulmonary Artery (Les grandes embolies de l'artère pulmonaire) *Lyon chir* 1946 41 143

The author has attempted to correlate the recent investigative work of his associates and others, which adds light to the problem of pulmonary embolism.

Of 222 patients who exhibited pulmonary emboli at autopsy 154 died with the clinical diagnosis of pulmonary embolism. In 132 cases the clinical diagnosis was correct. Those in 22 instances the clinical diagnosis was not substantiated by the autopsy findings. However in 90 cases pulmonary emboli which had not been suspected clinically were found at autopsy.

The causes of death among 22 patients wrongly suspected of having pulmonary emboli were pulmonary edema, pulmonary tuberculosis malignant endocarditis, anemia with cardiac failure ruptured aneurysm, bronchopneumonia, pleurisy and valvular pathology mitral stenosis cardiac malformations or unknown causes.

Among the 90 patients who had pulmonary emboli which had not been recognized clinically death had been attributed to one of the following conditions cardiac failure pleurisy cachexia myocarditis uremia, generalized arteriosclerosis myocardial infarction mitral disease, grippe cerebral hemorrhage cardiorenal disease pulmonary tuberculosis bronchopneumonia, or paraplegia and pyelitis.

Thus it is apparent that massive emboli do not always exhibit the dramatic clinical picture with which they are commonly associated and further more many more unrecognized massive emboli occur than false embolic syndromes.

In 70 per cent of the patients who had a clinical diagnosis of pulmonary embolism substantiated by autopsy a complete obstruction of the pulmonary trunk or of the right and left branches was found. In these cases death was the result of a mechanical obstruction to the pulmonary artery. In the remaining 30 per cent of the patients the embolus involved only a portion of the pulmonary tree, and death can not be attributed solely to mechanical obstruction. It is conceivable that a violent vasomotor reflex modifies the coronary and cerebral circulation to complete the effect of the mechanical obstruction.

Operative attacks on pulmonary emboli usually reveal a very long nonadherent clot sometimes 40 to 60 cm. in length. Multiple statistics indicate that emboli are usually produced in the first 5 post operative days. Phlebitis seldom occurs before the end of the first week. In the author's opinion phlebotrombosis precedes thrombophlebitis and the danger of massive embolism exists during the early period when the clot is attached at a limited point, essentially floating in the blood stream. Once inflammation occurs and the clot becomes fixed the risk diminishes.

The most common source of the clot is in the common or external iliac veins or their tributaries and not the deep veins of the calf of the leg. Once detached the clot travels rapidly and if it is not completely obliterative in the first few moments the pressure of the blood soon forces it to occlude the pulmonary artery. Secondary coagulation then adds to and completes the obstructive process. Death results from pulmonary cardiac, and cerebral embarrassment.

The diversity of clinical forms and the rapidity of death are a result of the volume of the embolus the manner in which it obstructs the pulmonary artery and its location. Sudden death represents an obliteration of the pulmonary trunk or of its two branches. Survival for several hours signifies obstruction of a major branch of the pulmonary artery. The infarction type of pulmonary embolus results from small emboli.

EDWARD W. GIBBS, M.D.

Törnelli, E.: Thresher's Lung. *Acta med. scand.*, 1946, 125: 191

Inhalation of dust of various kinds may give rise to pathological lung changes. The nature of these changes is determined by the physical and chemical composition of the inhaled particles, by the amount of dust and the length of the exposure and by individual susceptibility. The pneumoconioses develop after the inhalation of inorganic dust. In silicosis, which is typical, the occupation, together with the characteristic symptoms and the lung changes, generally points to the diagnosis.

Organic dust is much less injurious to the lung since it is more easily resorbed. It does not cause pneumoconiosis, with its typical fibrotic nodules. A massive inhalation may cause an atelectasis with hemorrhages and inflammatory changes that cannot be distinguished from pneumonia, and which ultimately results in chronic induration and bronchiectasis. Organic dust can, however, give rise to disease by serving as a medium for the introduction of bacteria and fungi. If the fungus is pathogenetic, mold disease of the lung develops—pneumomycosis, bronchomycosis or the disease may be named after the species of fungus involved, such as aspergilliosis, moniliosis, blastomycosis.

The primary form of bronchomycosis appears chiefly as an occupational disease in previously healthy persons. It is more common for the bronchomycosis to appear secondarily to other pulmonary disease. The fungus then covers the walls of existing cavities and may gradually spread, so that the mycosis predominates. It may even penetrate the vessels, and give rise to thromboses, infarcts, and hemorrhages.

"Tea tasters cough" is a primary bronchomycosis caused by the inhalation of tea dust containing *Monilia*. Isolated cases have been reported among dove breeders and wig makers. More frequently the disease is found among harvesters—bronchomycosis fenicislorum. This is a seasonal affection, and is due to the formation of mold on hay and grain. Some-

times the appearance of the disease coincides with threshing time.

There are 6 clearly delimited species of *Monilia*. Of these *Monilia albicans* is the only pathogen. It does not attack the mucous membranes of healthy animals or people. An increase in the degree of acidity of the membranes or their carbohydrate content is necessary for the growth of the fungus. Diabetes is a predisposing cause for fungal disease. The simultaneous inhalation of fungi and irritant dust containing dust as occurs in threshing is probably of importance. The virulence of the fungus seems to vary considerably both in different strains and in the same culture on different occasions. The cause for this variation is unknown, but individual resistance appears to be of great importance for the development of moniliosis.

Nine cases of thresher's lung are described. The diagnosis is arrived at through the history, the findings characteristic of pneumoconiosis, and the finding of fungi in the sputum.

The prophylaxis is more important than the treatment of thresher's lung. A protective mask should always be worn when "burned" grain is threshed. Persons who have difficulty in breathing through the nose should not engage in this work. Fences, stables, and other places of work where damp straw and grain are stored should be suspect. Farming men who acquire thresher's lung should receive compensation for it as an occupational disease.

SARAH KURT, M.D.

Bartlett, J. P. and Adams, W. E.: Solitary Primary Neurogenic Tumor of the Lung. *J. Th. Surg.* 1946, 15: 351

What is believed to be the first case of solitary primary neurogenic tumor (neurinoma) of the lung removed surgically is reported. Primary neurogenic tumors of the lung are extremely rare, although neurogenic tumors are commonly found in the mediastinum. Kent and associates added 18 cases to a summary of 105 thoracic neurogenic tumors from available medical periodicals inclusive to 1941. None of these was located in the lung. In a further search, especially of readily available English periodicals inclusive to November 1945, no neurogenic tumors of the lung have been discovered. A letter from the Tumor Registry Washington, D.C. states that there was no report of primary neurogenic tumors of the lung in the files.

Only during the past 30 years have primary neoplasms of the thorax been observed, studied, and reported in any numbers. From a clinical standpoint circumscribed hilar lesions may be simulated by peripheral circumscribed tumors and are, for the most part, confused with metastatic tumors and infections which are in the minority in occurrence. Alexander stated that contrary to the prevailing impression, the majority of circumscribed intrathoracic neoplasms are intrapulmonary and malignant. Many of these tumors which are benign undergo malignant changes, or cause disability

was distal to the bifurcation of the main-stem bronchus giving the impression of a dermoid cyst of the lower anterior mediastinum. Bronchoscopic examination was entirely negative. The surgical chest service at first considered the possibility of the tumor being an aneurysm of the aorta, but practically ruled this out by fluoroscopic examination. Its position in the mid-anterior mediastinum protruding into the left side of the chest did not seem to put it into a category of smooth walled neurogenic tumors which occur mainly in the posterior mediastinum, but was more suggestive of a dermoid of the anterior mediastinum. The lack of calcification in the wall did not rule out a tuberculoma. Malignant lymphoma had to be considered but these lesions are usually less circumscribed and the margins are less sharp and are lobulated. One might expect more symptoms if this were such a lesion. By size, location, and bronchoscopy, as well as lack of obstructive signs, a bronchiogenic carcinoma could not be ruled out. On the basis of size, location, great possibility of malignancy and the inability to make definite diagnosis, exploratory thoracotomy was advised.

On March 1, 1945, through a fourth left interspace incision the pleural cavity was explored. A hard spherical tumor mass was found in front and distal to the left hilum, lying for the most part free in the pleural space between the upper and lower lobes of the left lung. After incision of the pleura overlying the tumor, the tumor was readily freed down to the division of the left main bronchus where it was found firmly attached distal to the bifurcation of the left primary bronchus. It was so intimately and firmly attached to the bronchial wall that it was thought inadvisable to dissect the tumor free because of the danger of opening the bronchus or leaving the tumor behind. Biopsy was thought to offer more possibility of complications than assurance, therefore a left total pneumonectomy was performed in the usual manner.

The gross appearance of the tumor is illustrated in Figure 3. The tumor cut across through the bifurcation of the left main-stem bronchus and was firmly fixed to the outer layers of the bronchial wall. It was not possible to separate the tumor from the bronchus without destroying tissues of both. Within the tumor was a large irregular space partially surrounding a central mass. This space was filled with reddish brown, old bloodlike substances. The central mass was glary light yellowish-brown color and of soft consistency. The outer shell of the tumor tissue was a light yellow pink color and of a rubbery-firm consistency similar to that of peripheral fibrous tumors. The bronchial mucosa showed no evidence of tumor extension, but the upper lobe bronchus was partially occluded by the compression effect of the tumor.

The tumor was microscopically intimately attached to the bronchus and in some areas tumor tissue was separated from bronchial cartilage by a pseudocapsule of connective tissue 100 to 500 microns across. No actual invasion of the cartilage or

mucosa was seen in the sections taken. The tumor tissue had many mature venules and nerves and capillary spaces throughout. Its cytoplasm hyalinized veinlike structure was unusual when seen, and in this case the loose cellular structure of collagenous strands could not be differentiated from an organizing thrombus. Most of the nuclei were of any size showed definite intimal and proliferation of their walls. The outer tumor mass was composed of masses of swirling cells, varying from dense collagenouslike spindle cells with elongated nuclei and showing a tendency to form small aggregates, with alternate spaces of amorphous structure, to a very loose cellular structure of cells with clear or loose reticular vacuolation. Some of the cells resembled lipophages. Fat stains, with H. & E. IV showed neutral lipid substances in these cells and very little in other parts of the tumor. Iron carmalum stains contributed no positive information. On the margin of the tumor surface pointed into the bronchus, beneath lymphoid tissue containing intrathoracic pigment granules, were areas of what appeared at first impression (with hematoxylin and eosin stains) to be sclerotic arterioles, similar to the structures seen in lesions of a sclerotic angiosarcoma type. Further study of Van Gieson, Bodan, and Perdrau stained slides proved these areas to be concentric and circularly elongated nuclei of proliferating Schwann cells about nerve fibrils. (The microscopic appearance of these areas was almost identical to those reported by Bailey in 1938.)

JAY P. BARTLEY, MD

Olsen, A. M.: Boeck's Sarcoid: A Brief Review of Report of a Case in Which Diagnosis Was Made by Bronchoscopic Examination and Biopsy. *Ann. Otol. Rhinol.* 54:55, 1945.

In a case of Boeck's sarcoid, the history of the illness covers a period of 10 years. Lesions involved the lungs and the ninth and tenth cranial nerves. The diagnosis of sarcoidosis was established by bronchoscopic examination and biopsy of tissue taken from the bronchial mucosa. Roentgenograms of the thorax demonstrated the progression and regression of the pulmonary lesions in the course of 6 years. Gold sodium thiosulfate was administered after definite diagnosis had been established. It appeared to have been of benefit.

To the best of the author's knowledge, this is the only reported case of Boeck's sarcoid in which a diagnosis was made by bronchoscopic examination and biopsy of a bronchial lesion. Bronchial and bronchotracheal lesions of this disease have been demonstrated at autopsy, and there are reports of 5 cases of sarcoidosis of the larynx. Bronchoscopic examination was carried out in several patients suspected of having Boeck's sarcoid, but in no other instance has a tissue diagnosis from the bronchial mucosa been obtained.

The case reported is of particular interest because of the lesions of the cranial nerves. Involvement of cranial nerves has been reported not infrequently

accompanying sarcomatosis, but usually occurs in association with the uterovaginal form of the disease, and the seventh nerve is most commonly affected. The author feels justified in assuming that the lesions of the cranial nerves in this case were caused by sarcomatosis. The improvement in speech and deglutition is consistent with the course in many cases of sarcomatosis.

Boeck's sarcoma is a condition which must be kept constantly in mind by those interested in thoracic disease and bronchoscopy. Although this condition is most commonly confused with pulmonary tuberculosis and Hodgkin's disease, it also must be distinguished from primary or metastatic malignant disease of the lung, leukemia, pulmonary fibrosis, bronchiectasis, and fungous disease of the lung.

Leifer, I. L., and Herbst, P. A.: The Diagnosis of Bronchogenic Carcinoma by Examination of the Bronchial Secretions. *Ann. Otol. Rhinol.* 1946, 55: 646.

The authors present a diagnostic aid to supplement the procedures always employed in the diagnosis of bronchogenic carcinoma. This is the examination of the bronchial secretions and must not be confused with the study of sputum. It is of greatest value as an adjunct in cases which are completely inaccessible to bronchoscopic visualization. The authors believe that when more frequent roentgen examinations are made and all patients with questionable shadows are subjected to bronchoscopy examination so that secretion may be secured for cytologic study the diagnosis of bronchogenic carcinoma will be made early, more patients will be found suitable for treatment, and the prognosis of bronchogenic carcinoma will become more hopeful.

Three cases are reported briefly. Fifty-seven scored cases were cited in 47 of which diagnosis was made by cytologic study.

EMIL C. ROSENBERG, M.D.

Kauffman, K. E., and Neuhauf, H.: Mucocellular Papillary Adenocarcinoma of the Lung and Lobectomy. *J. Thorac. Surg.* 1946 15: 473.

Because of the variations in the literature concerning terminology with regard to mucous cell cancer of the lung it is virtually impossible to ascertain the incidence of this lesion. According to Neuburger and Geever who attempted a classification of the reported cases according to histology it is apparent that this type of tumor is not excessively rare. In fact, they believe that about 5 per cent of all primary cancers of the lung are of this variety. On the other hand it is also apparent that not a few of the cases in their collection are not sufficiently well documented to justify their being placed in this group. The difficulty becomes greater when an attempt is made to ascertain what, if any, distinctive features characterize this relatively rare form of cancer of the lung. Some cases are reported to be extremely malignant and of short duration and others are of comparatively long duration. There is no

other case reported with the topographical features of the authors' case and this is perhaps the reason that their case is the only one in which lobectomy rather than pneumonectomy was done.

In generalizing from the particular case, it would appear that a long standing unproductive cough, clubbing of the fingers, and a roentgenogram of the chest revealing a shadow with some suggestion of lobulation appear to comprise a triad pointing to a circumscribed type of cancer of the lung which may prove to be of the mucous cell type. Should bronchoscopy in such a case yield positive results it would be more in the nature of an accident of erosion of the tumor into one of the larger bronchi. The fact that the patient has responded well up to the present time to the relatively simple procedure of lobectomy emphasizes the fact that the tumor is circumscribed and well localized. The tumor involved almost the entire lobe in this case, but could nevertheless be eradicated by lobectomy with a satisfactory follow up 2 years after operation.

JOHN J. MALONEY, M.D.

Clagett, O. T., and Deterling, R. A., Jr.: A Technique for Segmental Pulmonary Resection with Particular Reference to Lingulectomy. *J. Thorac. Surg.* 1946 15: 227.

Great advances in thoracic surgery in the past two decades have reduced the mortality rate in lobectomy for suppurative pulmonary disease to below 5 per cent. Because of the prevalence and seriousness of bronchiectasis, early diagnosis is of particular importance in augmenting the number of cases in which surgical treatment is applicable. Emphasis should be laid on the role played by the lingular division of the left upper lobe in bronchiectasis.

A surgical technique for segmental pulmonary resection, with particular applicability to the lingula, has been described. By using the divided lingular bronchus for traction dissection the diseased bronchus, its subdivisions, and adjacent parenchyma may be simply and completely removed. Early re-expansion of pulmonary tissue is facilitated by the use of interrupted sutures and avoidance of clamps on normal pulmonary tissue. A review of cases in which this technique was used was presented and the complications of pulmonary resection were discussed.

HEART AND PERICARDIUM

Samson, P. C.: Two Unusual Cases of War Wounds of the Heart. *Surgery* 1946 20: 373.

Two unusual cases of cardiac trauma in soldiers, successfully treated, are presented.

The first case is that of a severe perforating wound of the heart by a shell fragment. The wound consisted of two 8 mm. lacerations of the left ventricle the wound of entrance was at the apex and that of exit in the midportion of the posterior left ventricular wall. Clinically the patient showed signs of shock but no dyspnea, hemoptysis or signs pointing

particularly to cardiac trauma. Operation was performed because a thoracoabdominal wound could not be ruled out in the face of a tender and resistant abdomen, persistent nausea and vomiting, and the apparent course of the bullet.

It seems that a rare chain of circumstances are responsible for the patient's surviving the original wound. It is probable that the fragment struck end on and passed through the heart without revolving during the diastolic phase thus irreparable damage to the papillary muscle was avoided. Also it must have come from the left and missed the diaphragm. The nausea and vomiting were probably cardiac in origin; these are uncommon in pure thoracic injuries. The fragment was found lying free in the pleural cavity.

The second patient, a German sergeant was wounded in the right posterior chest wall by a bullet that apparently ricocheted before striking him. He was admitted to the hospital 5 days after being hit. He showed little discomfort except for hemoptysis and moderate dyspnea. There was no evidence of cardiac pathology. Roentgenograms and fluoroscopy showed a foreign body that was movable but always remained within the cardiac shadow. At operation 7 days after the wounding, no laceration of either the pericardium or myocardium could be demonstrated. The foreign body, a .45 caliber bullet, was removed from the right ventricle and the patient was discharged from the hospital to weeks after operation.

It is obvious that the bullet did not traverse the heart because resultant damage would have been evident within the time limit stated. The foreign body evidently entered the venous system just outside of the pericardium and was washed into the right ventricle.

The author states that cardiomy for the removal of foreign bodies is not without risk, but also mentions a number of delayed complications that may arise from their presence. It is stated that unless localizing cardiac symptoms persist in most instances operation should not be considered an emergency.

Conclusions regarding the indications for cardiomy must await further clarification and critical comparison of results from operation and from conservative management.

EDWIN W. PAMARKILL, M.D.

Vesell, H., and Kroes, I: Patent Ductus Arteriosus with Subacute Bacterial Endarteritis: Diagnosis and Indications for Operation. *Arch. Int. Med.* 94: 67-75 1959

A case of patent ductus arteriosus, complicated by bacterial endarteritis, and successfully treated by means of both penicillin and surgery is reported in detail. The authors discuss the indications and contraindications for operation in cases of this type. A correct preoperative diagnosis involves consideration of the murmur, roentgenographic studies, the electrocardiogram, and blood pressure tests.

In the history it is usually found that the patient was not a "blue baby" but the child has had a history of cardiac murmur since infancy. Cyanosis does not occur except in the presence of pulmonary or cardiac complications.

The most helpful diagnostic sign was the type of a tunnel machinery murmur. It is loud, low pitched, rumbling and harsh, grows louder during systole, reaching its maximum intensity in late systole or early diastole, and continuing through most of diastole. It can best be heard in the left parasternal line in the second and third interspaces. The transmission of the murmur is quite uniform. Its quality component is well transmitted over most of the front and back of the chest, left and right; it can also be heard in the left axilla and in the neck. Its diastolic component, and consequently the continuous murmur as a whole, has been found by the authors to have a rectangular shaped area of transmission with the following borders: the midclavicular line to the right, the midclavicular line on the left, the third at the top and the fourth intercostal space at the bottom. The striking difference in size of the area of transmission of the diastolic component from the very much larger area for the systolic component suggests a different source or origin for each component. The presence of a continuous machinery murmur is not necessarily found in all cases of patent ductus; in some instances the murmur is limited to systole. In one of the authors' adult patients in whom this was the type of murmur, combined with operation revealed a very short, but not ductus. Rarely is a murmur lacking. A thrill is almost always felt over the pulmonary valve area. It can be felt better when the patient bends forward and holds his breath in deep expiration.

Frequently roentgenography is helpful in the diagnosis, particularly in the cases where the pathognomonic continuous murmur is absent. Enlargement of the pulmonary artery (roentgen-ray type of Zinn) with increased hilar and pulmonary markings (together referred to as Asman's sign) occurs in more than 50 per cent of the cases. Fluoroscopy reveals increased pulsation of the pulmonary artery in contrast to the feeble pulsation of the proximal pulmonary artery in mitral stenosis. The roentgenogram reveals the great amplitude of the wave produced by the increased pulsations of the pulmonary artery as well as some increase in the left ventricular border excursions. Angiocardiography brings out a characteristic and perhaps pathognomonic abnormality in the left oblique position: a small but definite bulge has been found in the aortic shadow at the site of the aortic infundibulum of the ductus in 16 of 27 cases. The size of the cardiac chambers may be normal.

The electrocardiogram is usually normal and is sometimes helpful in establishing the diagnosis by ruling out other conditions in which diagnostic changes are expected. There may be slight or moderate left axis deviation. Pronounced right axis deviation is strong evidence against the presence of

patent ductus arteriosus as an isolated or primary defect.

There is a characteristic alteration of the arterial blood pressure in most cases (Bohn test). The brachial artery diastolic pressure is commonly from 30 to 40 mm. of mercury below normal as in patients with a large arteriovenous aneurysm. There is usually a low normal systolic pressure.

The Bohn test was found of aid especially in the differential diagnosis of patent ductus arteriosus from an interatrial septal defect. This test consists of a substantial reduction of the diastolic blood pressure following exercise. A control reading of the blood pressure is taken with the patient standing. Then the blood pressure cuff is left on the arm, the patient exercises by taking 10 knee bends (or their equivalent). A blood pressure reading is taken immediately after exercising. The diagnostic sign is: occurrence of a substantial reduction of the diastolic pressure following exercise, elevation of the systolic pressure occurs, as it does in normal subjects. More than a minute elapses after completion of exercise, the characteristic blood pressure response may be missed. The sign has been further clarified by adding a second series of knee bends to exercise. In an 18 year old patient with patent ductus arteriosus and questionable cardiac decompensation the following blood pressure changes were obtained: control blood pressure in arm 125/50, after 10 knee bends, 165/0 and after 10 more knee bends, 205/0. Blood pressures in the legs (tibialis stipes) were control 162/90 after 10 knee bends 170/120, and after 10 more, 175/110. It is difficult to get satisfactory results, when this test is attempted in patients with endocarditis. In a patient with an interatrial septal defect, corroborated by phonocardiography a negative result was obtained. This suggests that a pronounced positive response with lowering of the diastolic blood pressure close to zero which often occurs after the second series of knee bends in patients with patent ductus arteriosus could favor the diagnosis of patent ductus arteriosus instead of that of interatrial septal defect in situations in which the 2 conditions are considered.

The diagnosis of a superimposed bacterial endocarditis should be considered when there are symptoms of weakness irritability anorexia, feeling of warmth with perspiration chills, cough, and loss of weight, together with an unexplained fever of a week or more especially when a history of recent dental extractions is given. In cases of bacterial endocarditis superimposed on a patent ductus, petechiae are common at the onset. Systemic embolization occurred much later in these cases than in the ordinary subacute bacterial endocarditis pulmonary emboli were more frequent. Hematuria was infrequent. Blood culture was positive early at times from 100 to 400 colonies per cubic centimeter of blood were obtained.

Prior to operative interference in a proved case of patent ductus arteriosus with subacute bacterial endocarditis, the possible presence of contraindications to operation have to be determined. There are 3 contraindications of importance.

The first is the presence of associated congenital cardiac anomalies for which the patent ductus represents a vital compensatory mechanism. Experience has shown that such associated anomalies are most uncommon after infancy and if present would be expected to be revealed in cyanosis from an associated pulmonary stenosis and the signs of coarctation of the aorta aortic stenosis or atresia. If one of these conditions were also present. Such associated lesions were not seen in the authors cases and are said to have been very rare in the cases reported. Septal defects either atrial or ventricular need not be a contraindication to operation.

The second contraindication to operation is extension of the infection beyond the ductus and especially to the left side of the heart. It has been advanced that operation on the ductus could not have any effect on bacterial vegetations in the aorta, on the mitral or aortic valves, and probably not even on vegetations on the pulmonary valve. It is objected that if this were true the high percentage of cures following operation would be difficult to explain. (Most series of cases reported in the literature show that the number of cases of patent ductus arteriosus with subacute endocarditis wherein the valves were spared are so few that up to 1931 only 5 cases had been reported.) Further if extension of the infection to the valves would destroy the chances of cure by ductal ligation, then on the basis of autopsy statistics recovery should not occur in from 65 to 85 per cent of the cases. One of the most important reasons for healing of the valvular infection following surgery is the elimination of the current through the ductus and of the infection in it by this procedure. A forceful blood current with strong eddies and turbulence, appears to be necessary for the development and maintenance of bacterial vegetations in the heart by favoring the production of fibrin necessary for the protection of bacterial growth.

There are 3 indications for operation in these cases.

1 When the causative organism, isolated by blood culture, is found to be penicillin insensitive in vitro.

2 Patients whose bacterial infection has been of long duration, irrespective of whether or not the etiological agent is sensitive to penicillin. The authors suggest that an arbitrary period of 3 months be taken as the period within which operation may be delayed. Reasons for operative interference in these patients would be to avoid extension of the bacterial invasion to other parts of the heart particularly to the left side where eradication of the infection would be more difficult.

3 When the organism which is sensitive to penicillin after a trial of several weeks of chemotherapy cannot be eradicated from the blood stream. Relapse which takes place shortly, may be only in the form of recurrence of the positive blood cultures with little or no fever (such as happened in the case reported in detail in the article). The decision to operate is made easier by either the imminence or pres-

ence of cardiac failure which, in itself is an indication for operation.

In addition to these indications the authors state that (1) the operative mortality is about 8.5 per cent for uncomplicated cases and 15 per cent for those with subacute bacterial endarteritis (2) life expectancy in patients with patent ductus arteriosus, even without infection is considerably below normal without operation the average age of the patients in Mande Abbott's series of fatal cases was 24 years.

EUGENE J. AUBE, M.D.

ESOPHAGUS AND MEDIASTINUM

Santi M: Pathogenic Varieties of Dilatation of the Esophagus (*Varietà patogenetiche del megacosofo*) *Riv. internaz. clin. ter.*, 1946, 26: 247

Dilatation of the esophagus may be caused by a stenosis of the cardiac sphincter from extrinsic factors such as a functional spasm of the periesophageal sphincter, an organic periesophageal fibrosis, or a mechanical dilatation of the esophagus. The intrinsic factors producing dilatation are functional spasm of the cardiac sphincter, caused by a disturbance of innervation such as lesions of the vagus nerve, and organic lesions resulting in chronic stenosis of the esophagus. A paralysis, atonia, or hypotonia of the wall of the esophagus may be congenital or acquired. The acquired form is caused by lesions of the vagus, disorders of innervation, or war gas.

The symptoms resulting from this condition depend upon the etiology. In a study of 3 cases, it was found that only dysphagia and vomiting was present in the first case while in the second case there was difficulty on swallowing, and a sense of obstruction which was more noticeable with solids. A sensation of having a lump at the region of the xiphoid was present, and a typical anginal retrosternal pain was experienced when lying down. It was therefore necessary for the patient to sleep in a semi-reclining position. Nocturnal cough, followed by vomiting, presents the problem of aspiration of the vomitus. Fainting on a reflex basis, due to compression of the cardiac or vagus nerves, was seen at times.

The diagnosis of megacosofo is dependent on the symptoms and x-ray findings, and this condition must be differentiated from tumors of the mediastinum, angina pectoris, diverticulum of the esophagus, aneurysm of the aorta, and carcinoma of the esophagus.

Because of complications such as pulmonary abscess or mediastinitis, the prognosis is poor.

The etiology determines the form of treatment. Medically the antispasmodics are useful however in some instances, such as the author's second case surgery was indicated and a cardiomyotomy was carried out.

ARTHUR F. CIOPIA, M.D.

Ramos, P: Peptic Ulcer of the Esophagus (*Úlcera péptica del esófago*) *Rev. gastroenter.* 1945 10: 371

Ramos discusses the different pathological conditions of the esophagus and particularly the peptic

ulcer. He reports the case of a 40 year old Mexican female who for 2 years had epigastric pain radiating to the back and lasting for a few minutes. She had the feeling that the food stopped before it passed into the stomach, and, in fact, learned that by very small amounts the distress decreased considerably. A small esophageal ulcer was found by x-ray examination.

The author discusses the pathogenesis, endopathology, symptomatology and treatment of ulcers of the esophagus. WILLIAM E. RICHARDS, M.D.

Engler, C. W: Perforation of the Esophagus Caused by Instrumentation. Review of 1 Cases. *Ann. Otol. Rhinol.*, 1946, 55: 607

In a series of 8 cases of perforation of the esophagus, the cause was a foreign body in 6 instances, of the remaining 2 cases there were acquired bronchoesophageal fistulas, 1 due to cancerization by regurgitated with suicidal intent and 1 due to syphilis.

Of the 6 patients with perforations caused by foreign bodies 3 were treated conservatively with spontaneous recovery. The 4 others were subjected to a mediastinotomy with recovery in 3 cases and died from a fulminating paroesophageal infection after the removal of the foreign body in the other. All patients with bronchoesophageal fistulas died, the first by suicide after discharge from the hospital and the other from the disease.

In all of the cases, roentgenographic examination and endoscopy were important in the diagnosis. In 6 of the cases of esophageal perforation caused by foreign bodies, the foreign bodies were not removed roentgenographically nor esophagoscopically and were not removed. Eight cases are reported in detail.

ELMER C. ROEMER, M.D.

Trolle, E., and Trolle, D: Treatment of Esophageal Varices by Injections of Sclerosing Agents through the Esophagoscope. *Acta chir. scand.*, 1946, 94: 385.

The authors report the case of a 24 year old male subject to severe recurrent attacks of hematemesis in which a diagnosis of splenic phlebostasis was finally made. The first hematemesis occurred in April, 1940.

In October 1941 he was operated upon with a diagnosis of ulcer but this was not confirmed. The presence of a normal liver and the absence of ascites with splenomegaly led to further investigation, which revealed esophageal varices.

Splenectomy was done in December, 1941. The spleen weighed 1,950 gm. In June, 1942 hematemesis recurred. Ligation of the coronary veins of the stomach was attempted in August, 1944, but extensive adhesions prevented this.

Injection of the varices under esophagoscopic control was begun in September 1945, with varices of the sclerosing solution (varix is 5% mono-actinal amino-oleate, of accepted sclerosing potency).

A total of 32 injections of from 1 to 8 cc. of varix (only once was quinine and urethane used) were of

d out over 30 months with apparent improvement
y to be followed by a recurrence of severe bleeding
months later

The patient committed suicide 23 months later
seen in the esophagus at postmortem examination
his result is striking in view of other favorable clinical
results in the literature. The possible reasons for
accused. It is hinted, however, that a better result
might be obtained if the solution were injected sub-
cutaneously or along the vein rather than intraven-
ously provided that a non necrosing substance
(see) be used.

HERMAN T. LAWTON M.D.

MISCELLANEOUS

—GROSS, A. F.: Massive Organizing Hemothorax.
Surgery 1946, 30 168.

Hemothorax in war surgery is often large, occupy-
ing most of the pleural cavity and compressing the
lung. Bony thorax injuries are severe with rib com-
minution and lung parenchymal damage by bony or
shell fragments. The blood coagulates and pockets
into large or small locules encompassed by fibrin
eventually this spongelike structure organizes in-
terstitial fibrosis, underlying collapsed lung and the
entire thorax undergoes an irreversible

permanent vital capacity reduction on exertion,
and occasional thoracic scoliosis. Experience shows
that the massive organizing hemothorax will not
clear up spontaneously but leads to a life of semi-
invalidism.

To avoid these results the practice of open thora-
cotomy evacuation of clots and decortication and
rapid re-expansion of the collapsed lung was the
policy adopted by thoracic surgeons during the war.
This article presents the details of the technical pro-
cedure which the author found valuable in accom-
plishing these ends.

Only about 10 per cent of initial hemothoraces go
to organization if prompt and repeated aspiration
is carried out. In the author's experience this
is not necessarily due to the presence of infection
Indications for operation are

- (1) The presence of a massive hemothorax in which
aspiration fails to obtain frank blood or yields only a
few cubic centimeters of thick dark blood or serum
- (2) In such cases a large caliber needle should be used
and aspiration should be done in at least two places.
- (3) A-ray examinations show massive clouding of
from half to all of one pleural cavity, often with pro-
nounced mediastinal shift and small fluid levels in
several loculi. Little or no improvement can be seen
in progressive roentgenograms. Organizing accumu-
lations involving more than 50 per cent of the pleural
space are best treated by thoracotomy those involv-
ing less respond well to conservative measures.

Most surgeons decide on operating between the
third and sixth weeks after the wounding. In order
to avoid irreversible changes in the lung the author

operates as soon as the diagnostic signs previously
mentioned have been found. None of the author's
patients were operated on before the eighth day
Many patients were too ill to be transported and
reached the hospital only after the fibrothorax was
well advanced.

Either intratracheal ether-oxygen or cyclopropane
anesthesia is satisfactory. Positive pressure is used
to avoid the danger of mediastinal shift.

A posterolateral incision large enough to admit the
operator's hand is made, and a segment of the
seventh rib on the left or the sixth rib on the right is
resected. Massive clots are removed by hand or suc-
tion the loculi are broken down, fibrous strands are
trimmed with scissors (avoiding those which might
maintain lung expansion) and the cavity is washed
out with saline solution. A varying amount of de-
cortication is carried out. The freed lung is re-
expanded with positive pressure just before the
pleural cavity is closed. A mushroom catheter is in-
serted in the posterior axillary line an interspace
below the second interspace and a smaller one is inserted
in the second interspace anteriorly. The former pro-
vides drainage and the latter evacuates air. One
hundred thousand units of penicillin are given
normal saline solution are used to wash out all re-
mains of the cavity and some are left in place. The
wound is closed in layers and a bronchoscope passed
before the patient leaves the operating table.

Postoperatively both catheters are connected to
sterile rubber tubes and immersed in a sterile water
bottle on the floor. The anterior catheter is removed
in 2 days the posterior after 5. Penicillin, given
daily intramuscularly and through the tube is given
aged Patients are usually up by the end of a week
and usually have smooth postoperative courses. The
author has had no deaths or serious complications. The
88 thoracotomies. Thirty patients healed promptly
with rapid re-expansion of the lung and the other 8
developed infection with delayed expansion and
empyema.

The author recommends rib resection because
(1) wide exposure and inspection of the pleural
cavity is allowed (2) airtight closure is made easier
(3) postoperative pain and discomfort is decreased
and (4) encircling pericostal sutures which cut
off the circulation to the ribs can be avoided.

The bacterial reports on aspirated fluid are mis-
leading because infection often is confined to one or a
few locules. Portions of the cortex when ground up
although the contained blood clot is sterile. Patho-
genic organisms may lie latent in cells or masses of
fibrin in the pleural cavity and these should be re-
moved with care and a minimum of trauma. Solid
clot, thick strong adhesions and clots should be re-
integration for sterility. Sluggish or soft fibrin easy dis-
integration on pressure, or a tendency toward
hemolysis or lavender hue are danger signals which
should indicate a low grade or latent infection at
operation.

The advisability of decortication arises once the clotted material is removed. Patients coming to operation from 1 to 3 weeks after injury can be decorticated readily and completely. The imprisoning layer peels away with relative ease leaving the salmon-pink and soot speckled visceral pleura. A minimal bleeding is encountered and re-expansion is readily achieved under positive pressure.

If the process has been present more than 3 weeks, the decortication is progressively more difficult. The fibrin layer is thicker, more tenacious, firm like leather and has become densely adherent to the pleura. Attempts to remove such tissue may lead to bleeding and contamination by tearing into the lung parenchyma. A cleavage plane usually can be found along the diaphragmatic surface of the lung and posteriorly in the vertebral gutter. During decortication an old bronchopleural fistula may be reopened. This should be avoided if possible, but if it should occur the opening may be closed with mattress sutures of chromic catgut. In late cases interstitial pleural fibrosis will prevent full immediate re-expansion. During decortication on the right side the thin walled azygos vein must be avoided. Decortication of the parietal pleura is not necessary and may excite bleeding. The object of decortication is maximal re-expansion of the lung and while the patient is in good condition and there is little bleeding from the freed surfaces, one should not cease his efforts to remove the investment completely.

While the author's early clean cases were closed without drainage, later experience led to catheter drainage in all cases. The postoperative accumulations of blood often cannot be removed by aspiration but can be removed by irrigation through a tube.

When the entire cavity develops suppuration a few days after operation, it usually is due to improper

selection of cases for early catheter removal and disregard for the gross pathological criteria previously mentioned which signal latent empyema. In several of these cases penicillin is ineffective, perhaps because of the presence of gram negative bacilli.

ROBERT R. BURLING M.D.

Poppe, E.: Hernia Diaphragmatica Dextra. *Acta radiol.*, Stockh., 1946, 27 505.

Diaphragmatic hernia occurs eight times as often on the left side as on the right, since the liver serves as a buffer for the right diaphragm, and external pressure occasions a far greater force on the unprotected left side of the diaphragm than on the right side.

Most diaphragmatic hernias are of congenital origin with the exception of those in which the hernia is produced by a perforating wound. The clinical diagnosis is difficult. No clinical symptoms are pathognomonic of the condition, but usually there is a combination of thoracic and abdominal symptoms which are often characteristic. Generally the diagnosis must be confirmed by roentgenograms.

Early diagnosis is important, so that operative treatment can be undertaken before irreparable damage has been done. The appearance of cardiac and respiratory complications, as well as the danger of strangulation should always be borne in mind. Operation at an early age is preferable since, if the viscera are allowed to remain in the chest for a long period, the abdomen will not develop sufficiently to accommodate the intestines when they are brought down later.

In several cases of diaphragmatic hernia on the left side and in 1 of the 2 cases on the right side, a gastric or duodenal ulcer was found.

SAMUEL KARR M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Isaacs, A. H.: Why Hernias Recur. *Am. J. Surg.* 1946
72: 550.

It is the author's contention that the inguinal region must be treated in relation to the dynamics of the area when inguinal hernia is corrected rather than being considered as a fixed anatomical specimen merely requiring the closure of any defects or holes present to correct herniation. He concurs with the opinion of W. J. Lytle of Sheffield (England) that the internal ring is mobile—an active mechanism of closure which under stress moves upward and outward under cover of the internal oblique and transverse muscle, and its action is therefore, that of a sliding valve and not of a shutter or a sphincter. Furthermore, the author indicates that the suture of the internal oblique and transverse abdominal muscle to the inguinal ligament is not only incorrect because union will not result, but the sutures destroy and weaken the muscle and together with the normal myodynamics of the muscle, interfere with the hernia.

He tabulates five types of recurrence (1) direct hernia, the most frequent (2) indirect hernia (3) saddlebag or pantaloon hernia (4) spigelian hernia along the semilunar line and (5) bladder hernia.

Recurrences are caused by inefficient surgical techniques and incorrect after treatment. The basis for the treatment of indirect inguinal hernia is high ligation of the sac and in direct hernia it is careful repair of the attenuated transversalis fascia. Care should always be taken when repair is made of one type of hernia to make sure that both types are not concurrently present.

Presurgical causes of recurrence are incorrect diagnosis improper choice of the type of repair and secondary conditions such as obesity, bronchiectasis, myocardiitis and active syphilis, which enhance the chance of failure.

During surgery many features are of importance in averting recurrence. Anesthesia must give satisfactory relaxation of the tissues without causing postoperative vomiting, straining or distention. Hemostasis careful asepsis proper placing of the incision, use of the drainage tube only when proper and careful choice of suture material are important. Evaluation of the existing defect by careful dissection and examination and then proper operative correction are important. Divided nerves failure to resect the spermatic cord in older patients or to abdominal ring in elderly patients failure to narrow the angle in elderly patients failure to narrow the angle are important causes of failure.

Postoperatively the author advocates postponing weight bearing until the scar tissue is consolidated, which takes about 7 days. He recommends avoid-

ance of coughing straining at bowel movements and attempting to rise up in bed. He advises against strain or hard work for 3 months after operation and as to patients over 45 with poor aponurosis he says they should never again return to laborious work.

Indirect hernia with a small internal ring is adequately corrected by ligation of the base of the sac alone. Mild stretching of the base of the sac by repair of the transversalis fascia and then imbrication of the external oblique fascia deep to the cord with the superior limb of the fascia sutured to the inguinal ligament and the inferior over it. In this procedure the conjoined tendon is undisturbed.

The Beach technique is also discussed in this flap of the external oblique is swung from a position lateral to the internal inguinal ring to a position medial to it and deep to the cord structures which has the effect of moving the internal ring laterally and of having the cord structures pass laterally and superiorly before they turn acutely in an inferior and medial direction. This adds gravity to the forces mitigating against recurrence.

In recurrences of direct hernia the author believes that principally because of inadequate dissection the bladder is frequently overlooked as a cause of recurrence. In the past he has corrected this by plication sutures in the bladder. He now believes because of recurrence in these cases that better results are obtained by excising and closing the portion of the bladder in the hernia.

The use of autogenous grafts is briefly discussed and great credence is placed in the livid pedicled fascia lata graft. FREDERICK C. HORN, M.D.

Brahm, Y. O.: Remarks Concerning Spiegel's Hernia (Consideraciones sobre las hernias de Spiegel). *Arch. Soc. cir. Hosp., Santiago*, 1946 16: 388.

A case of strangulated Spiegel's hernia on the left side is reported by the author. The majority of Spiegel's hernias occur at the insertion of the lateral border of the rectus muscle and a line connecting the anterior superior iliac spine.

Because of the great frequency of strangulations an operation is indicated whenever Spiegel's hernia is diagnosed unless some contraindications are present. If the hernia is not strangulated, an incision in the direction of the skin line should be made, the sac should be exposed, isolated, and ligated after resection of its contents and after closure of the peritoneum the aponeurosis should be imbricated. If the hernia is large, the muscles and aponeurosis should be sutured in the transverse direction because a suture in the longitudinal direction predisposes to recurrence. In extraordinarily large hernias plastic operations may be indicated and for this purpose the sartorius muscle or preferably the external oblique muscle and the rectus sheath may be used.

Reduction of the strangulated hernia is usually unsuccessful on account of intrasaccular adhesions and bands, which may be responsible for a spurious reduction.

The author's patient was a woman, age fifty-eight who had had a tumor in the left inguinal region for a number of years. Six years prior to admission she developed pain in the involved region with vomiting and meteorism. A diagnosis of a strangulated left inguinal hernia was made, but the operation established the correct diagnosis. After the adhesions between the omentum and the hernial sac were severed, the cyanotic strangulated loops of intestines assumed their normal color and were reduced into the abdominal cavity. The patient made an uneventful recovery. ARTHUR F. CROTTA, M.D.

Young, J. P., Jr., and Cole, W. H.: Intraperitoneal Administration of Succinylsulfathiazole and Phthalylsulfathiazole: Their Use in the Prophylaxis and Treatment of Peritonitis. *Arch. Surg.* 1946, 53: 182.

The authors used succinylsulfathiazole and phthalylsulfathiazole both in dogs and in a series of 18 human beings and demonstrated that when the dosage remained within the limits of 0.1 gm. per kilogram of body weight there were no toxic reactions. Careful studies of the urine did not reveal any crystalluria, and examination of the peritoneal cavity of the dogs did not reveal any tendency toward the formation of adhesions. The absorption of the drugs from the peritoneal cavity was rapid almost simulating that of sulfanilamide. The advantage of the two drugs over the sulfanilamide however was that they have a far more adverse effect against the *Escherichia coli*.

The rapid absorption of succinylsulfathiazole and phthalylsulfathiazole means that they are valuable only in the protection from soilage occurring at the time of the operation, and not for any later soilage which may come from a leaking suture line. In 2 cases the authors had the opportunity of observing the effect of the drugs on the *Escherichia coli*. One of these was a ruptured appendicitis and the other a perforation of the cecum secondary to a tuberculous ulcer. At the time of the operation mixed cultures were obtained containing the *Escherichia coli*, the staphylococcus, and the streptococcus. At autopsy only the coccal forms were found.

WILLIAM C. BECK, M.D.

GASTROINTESTINAL TRACT

Kavazdli, N. E.: The Antitreticular Cytotoxic Serum of Bogomolts in the Treatment of Gastrointestinal Diseases. *Vrachebno Delo* 1945, 26: 50.

The author's material comprises more than 200 cases of gastrointestinal ailments which were treated with Bogomolts' serum. All the patients were subjected to detailed study but since most of the cases have already been reported elsewhere this report is

limited to a discussion of the results obtained in the various groups as groups, with abbreviated case histories of 1 or 2 typical patients from 2 of the most important groups.

In the first group are included the patients with malignant neoplasms of the digestive organs, such as cancer of the esophagus, stomach, and small intestine, and to this group the author adds the cases of enterocolitis with grave exhaustion of the general condition (reticuloendothelial system). In the second group are included the patients with chronic colitis of medium severity, and the cases of severe, acute gastroenterocolitis. Finally the third group is made up of the gastric and duodenal ulcer cases and those of chronic gastritis with hyperacidity.

The purpose of this grouping is that of a closer study of dosage, and the author believes that with greater attention to dosage even better results than those recorded here may be attained. However in this report the author does not mention any modification of dosage and seems to have employed the standard practice of injecting 0.05 cc. of the serum intracutaneously into the skin of the upper arm in a first course of 3 injections at 3 day intervals, with perhaps a second course in a month or so when the patient shows indication of recurrence. It is emphasized however that this treatment is not directed against the pathological condition itself but against the concurrent depression (blockage) of the reticuloendothelial system, and these groupings are arranged according to the different degrees of depression of the physiological functioning of this system. No claim is made that the ACS (Peaks prefer the term "reticuloendothelial immune serum" [REISS]) should be used to the exclusion of other accepted methods of treatment directed against the pathological condition itself and in this material, with the exception of a few control patients, other methods such as dietotherapy and atropin were initiated and used concurrently with the injections.

A positive result with ACS was obtained in 50.7 per cent of the gastric and duodenal ulcer cases, with complete disappearance of all subjective and objective symptoms, including healing of the ulcer niche in 32 per cent, which was shown by roentgenography. Among the patients with chronic gastritis there was a complete disappearance of all symptoms in 33.3 per cent of cases, there was improvement in 50 per cent, and failure in 16.7 per cent. In 78.9 per cent of the anacid and subacid cases of gastritis there was an elevation of the acid component of the gastric contents, and in 15.8 per cent of those with gastric anacidity there was a development of free hydrochloric acid. In 75 per cent of those with hyperchlorhydria the acid content was lowered. Of the patients with symptoms of chronic colitis the majority responded with a disappearance of the diarrhea, a decrease of the pain and other symptoms, and a general improvement and feeling of well being.

Although it was thought that the chief indication for ACS in cancer was the prophylactic effect against recurrences, nevertheless the serum was given in 20

the King County Hospital, Seattle, Washington, from 1938 to 1944 inclusive. Many of the patients admitted were in a poor state of nutrition. Others were chronic alcoholics, old and neglected. Most of the emergency surgery was done by the Resident Staff and junior members of the Attending Staff.

The authors found obliteration of liver dullness a physical sign of some diagnostic value. The patient is placed on the left side for 4 or 5 minutes. If there is an appreciable amount of air in the abdomen, liver dullness will not be found. Shock was not a common finding. Only 7.2 per cent of the patients exhibited evidence of this condition. It is believed that when shock is present in perforated peptic ulcer it is due largely to the action of bile and pancreatic juice which is poured into the abdominal cavity. Later hypoalbuminemia and dehydration also play important roles.

In order to demonstrate pneumoperitoneum roentgenographically the patient is placed on the left side for at least 30 minutes, after which roentgenograms are taken with the patient in this position. The authors believe that a smaller amount of air can be detected by this maneuver than by having the patient in the upright position. In 6.6 per cent of cases the diagnosis was not recognized until autopsy. Most of the patients were moribund upon arrival.

Early in this study 17 patients with *forme fruste* ulcers were treated conservatively with death of 7. Since that time this method of treatment has been abandoned and it is used only in cases in which operation is refused. Surgical treatment was instituted in 138 patients. The authors prefer a transverse incision of about 3 inches in length. The ulcer is closed with a living tag of omentum, and no sulfonamide drugs are introduced into the abdomen or the incision nor are drains inserted. A high percentage of these patients require no further operations after closure of the perforation.

The closure of the abdominal wound with heavy catgut is contraindicated because of the exudate that accompanies its use. Cotton or preferably wire sutures have been found to be most efficacious. Adequate serum protein and ascorbic acid levels must be maintained.

Among the cases reported there were 24 wound infections and 14 wound dehiscences. The overall mortality in this series was 27.7 per cent, most of the deaths being due to peritonitis and pulmonary complications. The authors present an outline for the general management of perforated peptic ulcer which should be of benefit to those interested in developing the routine for the management of such cases.

HAROLD LAUFMAN, M.D.

Bechrach, W. H., Grossman, M. I., and Ivy, A. C.: Problems in the Etiology of Peptic Ulcer; the Resistance of the Gastrointestinal Tract to the Digestive Action of Its Own Secretions. *Gastroenterology* 1946, 6: 583.

The authors re-examination of the question of why the stomach resists digestion by its own fer-

ments, includes a brief summary of the views on this question held by other workers, together with a discussion of present day concepts of this problem. The following factors are considered:

Resistance of the gastric gland. Studies have shown that in experiments wherein from 0.4 to 0.6 per cent hydrochloric acid is kept in continuous contact with the lining of the stomach, injury occurs first at the pyloric rather than at the fundic area (HCl formed by the parietal cells has a concentration of 0.58 per cent.) The reason why the surface epithelium of that portion of the gastric mucosa which forms acid can tolerate a more or less continuous contact with a solution of 0.58 per cent HCl is unknown at present.

The resistance of the surface epithelium. There is a gradient of susceptibility to acid injury in the gastrointestinal tract. The further away the mucosa from the source of acid formation, the less the resistance of the surface epithelium to injury by acid. Factors responsible for this are probably the epithelial cell structure, the role of the external secretions of the alimentary tract and the blood supply.

The resistance of muscle cells, connective tissue, and fibroblasts, or the resistance of a chronic ulcer to healing. Failure of penetration of an acute ulcer to the serosa (because muscle cells and fibroblasts grown in tissue cultures are killed by exposure to a concentration of HCl similar to that found in the stomach) results from transudation of plasma and the formation of a fibrin coat to buffer the acid and protect the underlying cells, renewal of the exposed surface of newly proliferated fibroblasts, and the possible protective action of mucoid cells growing out to cover the fibroblasts.

It is suggested that there is usually little difference between the potential rate of healing of the acute ulcer of a nonulcerous patient and the "chronic" lesion of an individual with peptic ulcer. A well-controlled series of experiments has shown that in the majority of cases the crater of a gastric or duodenal ulcer disappears within 6 weeks after the patient is placed on strict ulcer management.

The ulcer patient can be described as being one with either a normally resistant upper gastrointestinal mucosa subjected to excessive trauma from abnormally high gastric secretions, or a less resistant mucosa susceptible to injury at normal acid-pepsin levels. The therapeutic desideratum would therefore be to find a physiologically innocuous and non-destructive method to control secretion or to improve the resistance and proliferative activity of the cells because this would heal the acute lesion from which all chronic lesions originate and recurrence would be prevented.

EDWARD J. AUST, M.D.

Harper, W. H., and Lammner, R. A.: Necrosis and Ulceration of the Intestinal Wall in Simple Intestinal Obstruction. *Bull. Johns Hopkins Hosp.* 1946, 79: 807.

Simple intestinal obstruction was artificially produced in 10 dogs at the level of the ligament of

Treitz 20 cm. below the pylorus, in 10 dogs in the mid ileum, 100 cm. distal to the ligament of Treitz, and in 10 dogs in the terminal ileum 5 cm proximal to the ileocecal junction. The obstruction was produced by dividing the intestine between Stone clamps, and inverting both ends of the cut intestine by the Parker Kerr method. Food was withheld for 24 hours before operation and for the duration of life after operation. All dogs were allowed to drink water to 1,000 c.c. a day but received no electrolytes.

The results of this series of experiments show that damage to the intestinal wall occurred in none of the dogs with high intestinal obstruction in 70 per cent of the dogs with mid ileal obstruction and in 80 per cent of the dogs with terminal ileal obstruction. There was no hemorrhage or necrosis in high obstruction there was an average of 9.6 sq. cm. of necrosis in mid ileal obstruction, and an average of 18.3 sq. cm. of necrosis in low ileal obstruction. Actual ulceration did not occur in any animal with high obstruction, in 30 per cent of the animals with mid ileal obstructions, and in 30 per cent of animals with low ileal obstructions. There were no cases of gross perforation of the intestine followed by peritonitis. The lower the obstruction, the greater was the distension and the sooner it occurred. Kinking of the bowel, with formation of partially or completely obstructed isolated loops with an intact blood supply occurred in no case of high obstruction but did occur in most cases of mid ileal or low obstruction.

It is interesting to note that the results of this series of experiments indicate that when water is given ad libitum to dogs with simple obstruction the well established concept, i.e. the higher the obstruction the less the survival time no longer holds. Instead it was found that dogs with high obstruction live longer than those with low obstruction.

Activated pancreatic juice is not an important cause of necrosis or ulceration of the intestinal wall in simple intestinal obstruction since the area and incidence of necrosis and ulceration were greater in the lower obstructions, whereas the pancreatic activity of the intestinal content found at the lower levels was less.

The normal intestinal bacteria, acting upon tissue whose resistance has been lowered by ischemia due to distension are responsible for the ulceration of the intestinal wall that occurs in simple intestinal obstruction. The lower the obstruction, the greater is the incidence of positive peritoneal and heart blood cultures found at autopsy. **SAMUEL KAHN, M.D.**

Caster, M. R., Udaondo, C. B. and D'Alotto, V.: Primary Cancer of the Duodenum (Cáncer primitivo del duodeno). *Prensa méd. argent.* 1946 33 1479.

In a study of 7 cases of primary carcinoma of the duodenum seen by the authors, 65 per cent of the lesions were found in the region of the ampulla, 22 per cent were supra-ampullar, and 13 per cent were found in the infra-ampullar region. Adenocarcinomas were most frequently found and those in the first and

third segment were annular and followed the lymphatic distribution closely. Ulcerations were seen early with prominent irregular borders. Although metastases and glandular involvement were infrequent, occasionally there was invasion of the neighboring organs.

The clinical symptoms depended upon the site of the lesion and the degree of invasion, as some of the tumors caused no disturbance until stenosis was produced. Those in the duodenal cap or supra-ampullar region often simulated pyloric involvement producing an ulcerlike pain and vomiting of a nonbiliary substance. Melena and occult hemorrhages were common constipation was constant and a palpable mass was found in one third of the cases. The x rays revealed filling defects and stenosis.

Carcinoma of the second part of the duodenum was found most frequently over the ampulla of Vater or nearby. It produced an early involvement of the common duct, which resulted in jaundice and signs of infection in the biliary system. Hepatomegaly and biliary distension were seen in one-third of the cases. Differentiation from carcinoma of the pancreas is difficult. Hematemesis and profuse melena are early symptoms.

The lesions in the third part of the duodenum give rise to vague symptoms of dyspepsia due to stenosis. Distension above the stenosis and filling defects may be visualized by means of the x rays.

The prognosis of undiagnosed carcinoma of the duodenum is death in a short time. Surgery is more successful when the diagnosis is made early and the general condition of the patient is good, while the type of operation depends on the site and extension of the tumor. **ARTHUR F. CIRIELLO, M.D.**

Costich, K. J., and McNamara, W. L.: Carcinoma of Meckel's Diverticulum. *Ann. Surg.* 1946 124 503.

The literature on tumors of Meckel's diverticulum is reviewed and a new case is reported. The present report brings the total number of cases of this type to 9. In 6 cases the tumors were adenocarcinomas of intestinal mucosa, in 1 case an adenocarcinoma of gastric mucosa, and in 2 cases medullary carcinomas.

Clinically it is very difficult to make a diagnosis of tumor of Meckel's diverticulum before operation or autopsy. The most common symptoms lead to the impression of an acute pathological lesion in the abdomen. The tumor may or may not be palpable, and symptoms do not depend upon the size of the tumor. Complications such as intestinal bleeding, intussusception obstruction or perforation with either local or diffuse peritonitis, may be responsible for calling attention to the condition. Occasionally the lesion can be demonstrated roentgenographically although it is impossible to differentiate an inflammatory lesion from a malignant one.

The case reported is that of a 55 year-old colored male who was admitted to the hospital with acute sharp pain in the abdomen and a history of a similar mild attack some 3 weeks previously. Physical ex-

amination pointed to a diagnosis of acute appendicitis. Exploration revealed a normal appendix in an abdomen containing seropurulent material. The tumor mass of the ileum was exteriorized for later removal. The patient died 6 days later and at autopsy a marked ileus with distension of the entire small bowel above the exteriorized mass was revealed. Sections of the tumor proved it to be an adenocarcinoma of Meckel's diverticulum.

HAROLD LAUTMAN, M.D.

Beston, E. D. S.: Cancer of Right Colon (Cancer do colon direito). *Rev cir S Paulo* 1946, 11: 261.

Statistics show a steady increase in the incidence of cancer of the colon; however they show also an increase of operability and a decrease of postoperative mortality.

Any lesion which can be mobilized after ample exposure and which does not involve vital structures, is resectable. Adhesions involving one ureter, one kidney, the stomach, the duodenum, loops of small intestine, pancreas, gall bladder, spleen, and the margin of the liver form no contraindication to the removal of the lesion.

Of 9 cases observed by the author the tumor was located in the left colon in 6 patients, and in the right colon in 3 patients.

Visible blood in the stools was found in 97.7 per cent of cancers of the rectum, in 46 per cent of those in the left colon, and in only 9 per cent of the malignant lesions of the right colon. Metastases appear relatively late.

The author advocates right hemicolectomy with terminalateral anastomosis of the ileum to the transverse colon.

JOSEPH K. NARAT, M.D.

Simon, H. E., and Williamson, B.: Prolapse of the Rectum. *South Surgeon*, 1946, 11: 139.

Cases illustrating the various types of rectal prolapse and their treatment are presented. The great number of surgical procedures that have been suggested particularly for complete rectal prolapse makes the selection of the most appropriate difficult. However since Moschowitz considered the condition a hernia, his suggested cul-de-sac obliteration operation has been considered by many as the operation of choice in the treatment of uncomplicated complete and high prolapse. It is easily accomplished, has a low surgical risk, and accomplishes a high percentage of cure.

In the presence of strangulation and gangrene, amputation of the rectum by ligation over a tube is probably the operation of choice, although stricture must be guarded against and the Moschowitz operation may be necessary later to attain permanent cure. Coincidental cystocele, rectocele, or uterine prolapse should be repaired shortly before or after or at the same time that the Moschowitz operation is done, according to the condition of the patient. Before the menopause, tubal ligation is indicated because pregnancy would favor recurrence. The persistence or appearance of a small amount of

prolapse postoperatively is frequently due to a coincident mucosal prolapse and may require a supplemental operation for its correction.

JOSEPH GARTER, M.D.

Colcock, B. P.: Perforating Wounds of the Colon and Rectum. *Am. J. Surg.* 1946, 72: 343.

The primary objective in the treatment of perforating wounds of the colon, just as in the treatment of battle wounds of any other type, is the preservation of the patient's life. To accomplish this in as high a percentage of patients as possible, three fundamental principles must be kept in mind: first, the perforation must be dealt with in such a manner that a further leakage of intestinal contents into the peritoneal cavity is prevented; second, the manner of closure must be such that there is no marked impairment of the bowel lumen; and last, the procedure should be one that will add a minimum of shock to a patient already suffering from exposure, loss of blood, and the trauma of a severe wound. The colon wound is usually associated with multiple wounds of the small bowel and other abdominal viscera and often with wounds of the extremities, perineum, buttocks, and other parts of the body.

That marked progress toward this primary objective has been achieved is shown by a comparison of the mortality figures of patients with perforating wounds of the abdomen operated upon during the recent conflict with mortality figures for similar groups of patients operated on during World War I. Then the mortality rate ranged from 50 to 75 per cent. In this war it has dropped to the neighborhood of 30 per cent. This includes those dying in the general hospital, sometimes weeks after their injury, and is a tribute to the Medical Corps of the armed forces of the United States. The progress which has been made is the result, partly, of the early and adequate replacement of blood loss; it is frequently necessary to give blood to those patients in amounts as high as 3,000 to 4,000 c.c. during the first 12 hours. It is also partly the result of the extensive use of the sulfonamide drugs and penicillin, both intraperitoneally and parenterally, and it is due chiefly to the high degree of technical skill employed by the surgeons operating in our forward hospitals. The development of the highly trained surgical team consisting of surgeon, assistant, anesthetist and surgical nurse, often augmented by a medical officer trained in the treatment of shock, is one of the most significant advances made in the field of military surgery during this war. The widespread use of such teams in the field and evacuation hospitals, operating usually within a few miles of the front lines, has saved many battle casualties which a few years ago would have been considered hopeless from the standpoint of military surgery.

As the mortality decreased, it became possible to concentrate on a secondary objective, namely to decrease the high morbidity associated with these wounds. All too often separation of the laparotomy incision, retraction of the colostomy and the formation

tion of intraperitoneal and subphrenic abscesses followed the successful primary treatment of the wound. Frequently these complications were sufficiently serious to jeopardize the life of the patient.

Exteriorization of the injured segment of the colon has become an accepted principle in the treatment of the majority of perforating wounds of the large bowel yet in 28 per cent of the first group of 25 cases the colostomy stoma was at the level of the skin or beneath when the patients were admitted to the general hospital. In 25 per cent of this group abscesses of the abdominal wall, of the adjacent peritoneal cavity or subphrenic space occurred.

It is obvious that the bowel must not only be exteriorized but it must be exteriorized without tension. If there is any tension on the exteriorized segment, it will inevitably retract regardless of the type of support which is used to hold it above the skin. Exteriorization without tension as well as the formation of a spur of adequate length if such a spur is desired, is dependent on adequate initial mobilization of the visceral and parietal peritoneum and mobilization of the mesentery of the bowel to its central attachments on the posterior abdominal wall, it is possible to exteriorize any segment of the colon terminal ileum or sigmoid at some point on the abdominal wall without tension.

The only difference of opinion concerning one of the essential points in the treatment of rectal perforations namely the drainage of the perirectal space is as to whether or not it is necessary to remove the coccyx. There were 7 patients in this group in each of whom the coccyx was not removed at the time drainage was established. No instance of abscess formation as a result of inadequate drainage was observed nor has it occurred in previous experience with cases of this type in which the coccyx was removed. The fundamental principle however is the adequate drainage of contaminated areas. If because of the particular type of injury concerned or because of the limited previous experience with this type of injury the operator believes that he cannot adequately drain the perirectal space without removal of the coccyx, he should by all means remove it. If on the other hand, he believes adequate drainage can be obtained by dividing the fascia propria transversely at the tip of the coccyx carrying any muscles if necessary then the coccyx is better left undisturbed.

The surgical management of wounds of the cecum ileocecal valve colon rectosigmoid, and rectum is discussed. A summary of end results is included.

Marked progress has been made in military surgery during the course of the recent war. The lessons learned must not be forgotten. The problems raised must be followed through and the best solutions possible be found so that the military surgeon of tomorrow may begin not where the military surgeon of today began but rather well beyond where he finished.

JOHN E. KIRKPATRICK, M.D.

Hamilton, J. E., and Cattanauch L. M.: Reconstruction of War Wounds of the Colon and Rectum. *Surgery* 1946 30 337

This article is based on the experiences in reconstructing 43 colostomies and 5 traumatic rectal fistulas in 41 patients at Crile General Hospital, Cleveland, Ohio. The closure of these colostomies is different than that of civilian colostomies because of the associated battle injuries which produce complications and the lack of details of construction.

Most of the patients were fatigued and malnourished averaging 117 pounds under their best weight at the time of surgery. The average preoperative build up period was 25 days during which they received a high caloric, high protein and high carbohydrate diet supplemented by multivitamin capsules a day. Those responding poorly received amino acids both in powder form by mouth and in 5 per cent solution by vein. Several examples are cited to emphasize the outstanding value of these amino acid mixtures in hastening the restoration of depleted and debilitated patients. Patients with even mild anemia were transfused preoperatively.

Five of the colostomies were closed by the extraperitoneal method the remainder were managed by intraperitoneal closures. In 5 cases end to end closures had to be done.

Preoperatively, a barium study of the distal loop small bowel studies if obstruction or other derangements of the small bowel were suspected and lipiodol studies of all sinuses and fistulas were carried out. In this way four abnormal sinuses or fistulas were discovered which otherwise might have been overlooked.

For 5 days prior to closure 12 gm. of sulfasuxidine were given daily in divided doses and 2 gm. suspended in 2 oz. of water were instilled in the distal loop of the colostomy. No laxative was used and both loops were irrigated with tap water the night before operation. In only 1 case was the drug continued postoperatively. From 3 to 5 gm. of sulfanilamide crystals were applied locally at the time of operation. Postoperatively for several days, 21 patients received penicillin (from \$5,000 to 40,000 units intramuscularly every 3 hours) and 17 received sulfadiazine therapy (first by vein then 1 gm. every 4 hours by mouth). The authors stress their confidence in the use of sulfasuxidine.

There was no significant difference between the patients receiving penicillin and those receiving sulfadiazine postoperatively. Wound healing was complete in 10.4 days in 34 patients receiving sulfadiazine, and they were allowed out of bed in 10 to 15 days.

Anal dilatation and Wangenstein suction for from 30 to 72 hours were used for decompression. Most patients received from 500 to 1,000 c.c. of plasma during or after operation and blood if necessary. Thereafter from 1 to 2 liters each of amino acids and 5 per cent glucose in saline solution were used to maintain hydration.

Intraperitoneal closures were used exclusively in 38 of the colostomies. With sharp dissection and

silk technique" all scar tissue and skin were trimmed away from the stomas and the 2 colonic limbs were inspected. Local adhesions were left whenever possible and when the limbs were fused at their mesenteric border the adhesions were left undisturbed to buttress the closure. A transverse closure was carried out with an inner row of sutures of fine chromic gut including all layers and an outer inverting row of interrupted Cushing sutures of fine cotton, palms being taken to include the submucosa. Any disparity in the size of the lumens was corrected by incising backward from the mouth of the smaller limb along the antimesenteric border and rounding off the corners. None of the 38 patients with intraperitoneal closure has had any sign of obstruction or break down. The one mucous fistula closed spontaneously by the ninetyeth day.

The authors do not crush the spur because it is disagreeable or painful to the patient and because of the inadequate information available as to the original colostomy construction. Spur crushing in these cases might cause a jejuno-colic fistula or endanger the blood supply.

In most cases the abdomen was closed in layers with cotton and silk and occasionally a rubber drain was placed to the peritoneum or fascia. The wounds nearly all healed per primam. The delayed closure method of Collier and Valk was not employed. A case report of one of the more difficult intraperitoneal closures is given in detail.

The 8 extraperitoneal closures included 3 unsuccessful ones which were performed overseas. Later the authors made successful closure intraperitoneally. Recurrence of fecal fistula with failure of closure took place in 3 patients, in 1 of whom closure had been attempted twice. Three patients developed intestinal obstruction and 1 died of it. The 7 complications or failures among the 8 extraperitoneal closures have led the authors to favor the intraperitoneal closure as being safer and far more satisfactory.

The authors have closed 6 traumatic rectal fistulas, and in each case the internal opening could be palpated on digital examination. Often the seriousness of these fistulas is underestimated. They tend to recur. From one-quarter to one half of the rectal circumference may be replaced with dense non-epithelialized scar often associated with stricture or an abscess pocket.

In repair complete diversion of the fecal stream is necessary. Adequate exposure often requires a generous incision with removal of the coccyx and of the fifth and sometimes the fourth sacral segment. Freeing the rectum from scar tissue is essential in order to permit closure without tension. Stenosis, if present, should be corrected as in a pyloroplasty by longitudinal incisions into the wall away from the fistula and then a transverse closure. The authors use a double tier of fine interrupted cotton sutures, the inner one through and through and the outer one inverting. A third layer may sometimes be made of the scarred fascia propria. Complete wound closure

is usually impossible and final healing takes place by granulation. All 6 fistulas were successfully closed. A case which showed a traumatic stricture to an abscess cavity containing a metallic foreign body is presented in detail.

ROBERT R. BENTLEY M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Hershey C. D.: Partial Hepatectomy in Certain Primary Tumors of the Liver. *South. Surgeon*, 1946, 12: 245.

Tumors situated in the left lobe of the liver are more easily and safely removed by lobectomy. A case report is presented in which the left lobe of the liver was completely removed with a successful result.

The patient was a 24 year old girl and the pathological diagnosis was hepatoma. The right lobe of the liver appeared entirely normal. The left hepatic artery the left branch of the portal vein, and the left hepatic duct were ligated with sutures of chromic catgut. An additional row of mattress sutures of chromic catgut was placed along the interlobar sulcus along the relatively avascular line of the lobes. The postoperative course was essentially uneventful.

A recent review of the world literature revealed 33 reported cases of resection of solid adenoma of the liver. There were also 223 cases of resection of liver tumors.

RICHARD J. BROWNE, JR., M.D.

Johnstone, G. A., and Ostendorp, J. E.: Cholecystitis with Perforation. *Arch. Surg.* 1946, 51: 1.

Of 12,000 routine autopsies performed at the Los Angeles County Hospital from April, 1936 to January 1945 the cause of death in 32 patients (0.26%) was found to be perforation of the gall bladder. Twenty-eight of the patients had been treated by conservative medical management, and in one-half the cases the condition had been undiagnosed prior to autopsy. Two of the patients had had surgery primarily for cholecystectomy and 4, for exploratory laparotomy.

On the basis of these findings the authors contend that perforation of the gall bladder is neither a rare condition nor seldom fatal. In contradistinction to the belief sometimes held that free perforation is infrequent or that when it occurs the morbid process is "walled off," acute generalized peritonitis was found present in 43 per cent of all cases of perforation.

For purposes of comparison, 105 consecutive cases of cholecystitis in which operation was performed were reviewed, and it was found that the overall mortality rate was 8.3 per cent. When more than 7 days after the onset of the illness had elapsed, the mortality rate rose to 11.4 per cent. In cases in which surgery was done during the first 48 hours, the mortality rate was 5.8 per cent, from which a rate of 2.9 per cent obtains if allowance is made for surgical accident. In 86 of the cases cholecystectomy was performed, and in 18, cholecystostomy. The authors state that surgery was carried out by not

one or two surgical teams, but by a considerable number of operators including surgical specialists, general practitioners, and occasional surgeons. Because of this, their mortality figures have undoubtedly been raised but it is believed that these figures indicate the advisability and safety of early cholecystectomy. Removal of the gall bladder is the procedure of choice in that the fundamental pathological process is thereby eradicated.

WAYNE CAMERON, M.D.

Gatch W D, Batterby J S., and Wadkin, K. G.: The Treatment of Cholecystitis. *J Am M Ass* 1946, 132: 119.

The idea that infection is the sole cause of cholecystitis still prevails and still governs its treatment. Conversely the idea that cholecystitis is caused primarily by chemical action has made slow headway although the reasons for believing it are compelling.

The pertinent facts on the relationship of infection to cholecystitis are the following:

1 Cholecystitis is rare in children, although infections are more commonly observed in children than in adults.

2 In about two-thirds of all cases of cholecystitis, the bile is sterile. The bacterial flora of the normal gall bladder and that of the inflamed gall bladder are the same.

3 The microscopic appearance of the inflamed gall bladder is almost never that of inflammation due to bacteria.

Abdominal wounds for the treatment of acutely inflamed gall bladders almost always heal without infection. On the other hand, numerous observations on injuries to the gall bladder by chemical agents have been made.

We have positive proof that pancreatic juice can cause acute cholecystitis in man, but we lack proof that it is the common or even a frequent, cause. The demonstration of the presence of amylase in high titer or of lipase in the contents of the gall bladder or in the peritoneal fluid is the only conclusive proof that a given case of cholecystitis is due to the action of pancreatic juice.

The bile salts are the only other chemical agents normally present in the body which have been proved to be able to cause cholecystitis in the experimental animal. That they can produce it in man has not yet been demonstrated although the probability that they can do so is strong. The authors have studied this problem in 4 series of experiments.

Series 1 Injecting solutions of bile salts into the gall bladder through a catheter.

Series 2 Injecting a 5 per cent solution of sodium desoxycholate, sodium taurocholate, or sodium glycocholate into a branch of the portal vein.

Series 3 Injecting a solution of activated pancreatic juice into the ampulla of Vater.

Series 4 Injecting bile salts into the portal venous system after ligation of the cystic duct, or keeping the gallbladder empty and squeezing it at intervals.

In the first 3 series the effects were immediate. There was edema, hemorrhage, and inflammation. In the fourth series the gall bladder showed no changes from normal.

In considering the clinical applications of the data obtained from the 4 series of experiments certain questions arise:

1 *Is early operation for acute cholecystitis the proper treatment?* The opinion is given that about equally good results can be obtained by either early or late operation, provided the surgeon uses good judgment on the individual case. Thus, if the inflammation is violent and the symptoms are growing progressively worse an early operation should be performed to avoid the dangers of perforation of the gall bladder. The fact that the gall bladder quickly recovers from chemical injury of rather pronounced severity supports the practice of postponing operation on patients whose symptoms are of moderate severity and nonprogressive.

2 *Is the gallbladder ever a focus of infection?* The removal of a gall bladder which does not show signs of disease on the theory that it is a focus of infection can no longer be justified. The mere presence of bacteria in the gall bladder does not indicate that they are injuring the gall bladder or any other part of the body.

3 *Is prolonged drainage of the gall bladder or of the common duct in the absence of jaundice in the hope of ridding the liver and biliary system of infection justified?* No. The absence of bile from the intestine hinders the digestion of fats and the absorption of fat soluble vitamins.

4 *Is there any danger in opening the gall bladder and removing its contents in performing cholecystectomy?* No failure to resort to this procedure often makes cholecystectomy a needlessly dangerous operation. This is true especially when the gall bladder is greatly distended or when adhesions surround the gall bladder and cystic duct.

5 *Should the common bile duct be opened when the tissues around it are edematous or when the head of the pancreas is thickened?* No, because it may have been severely damaged by activated pancreatic juice. Its incision and exploration in this event may cause its rupture or occlusion. Its exploration may prove unnecessary. It can be explored with safety at a second operation if signs of occlusion persist.

STEPHEN A. ZIDMAN, M.D.

Munilla, A.: Congenital Malformations of the Extrahepatic Biliary Tract with Subhepatic Obstructive Jaundice (Malformaciones congénitas de las vías biliares extrahepáticas con ictericia obstructiva subhepática). *Arch. surg. med.*, 1946, 28: 331.

The author discusses the syndrome of subhepatic obstructive jaundice produced by malformations of the biliary tract and describes 6 cases of this condition.

The first patient was a newborn who a week after birth had an increase of his jaundice, a slight clinical

increase of the size of his liver and spleen, acholic stools, choluria and melena. The infant died at the age of 3 months. The autopsy showed an atresia of the hepatic duct, hepatic cirrhosis, and hypertrophy of the pyloric musculature.

The second patient was a 9 day old child who had progressive jaundice since birth. At autopsy the spleen was located in the left side and atresia of the biliary tract was noted.

The third patient also had progressive jaundice since birth, acholic stools, choluria, and hepatosplenomegaly. At operation atresia of the gall bladder and biliary tract was found.

A similar picture was found in a fourth patient with jaundice since birth, splenomegaly and ascites. At autopsy absence of the biliary tract was noted.

WILLIAM E. RICKETTS, M.D.

Welborn M. B. The Management of Common Duct Stone Missed at Operation. *S. Ath. Surgeon* 946: 2: 185.

Two cases of common duct stone missed at the time of operation and subsequently demonstrated by postoperative cholangiography are reported. In 1 case the overlooked stone was apparently fragmented by instillations of ether into the "T" tube and the fragments subsequently were expelled into the duodenum.

JOSEPH GASTER, M.D.

MISCELLANEOUS

Bingham, D. L. C.: Surgical Complications of Amebiasis. *Canad. M. Ass. J.* 946: 55: 34.

With the recent widespread distribution of Canadian soldiers throughout areas of the world where the incidence of amebiasis was high and the subsequent high incidence of amebic infection in these soldiers the author expects an increase in amebiasis and its complications in Canada where heretofore, it was uncommon. He presents a timely discussion of its surgical complications.

The active entamoeba histolytica penetrates living tissue and its usual portal is through the mucous membrane of the colon where it produces characteristic ulcers. From the submucosa the organism may penetrate the muscle and peritoneal layers and give rise to peritonitis, with or without visible perforation. It may be carried to the liver and from there the entamoeba may be deposited in the lung, spleen or brain. Therefore it is obvious that the manifestations of the disease will be quite protean with a wide variety of complications. These may be classified as follows:

Complications of the disease in the bowel, amebic hepatitis and its complications, complications due to more widespread dissemination.

The more important surgical complications of the disease in the large bowel are pericolic infection with or without perforation, pseudo appendicitis, hemorrhage, and amebic granuloma.

Pericolic infections are most common in the cecal region and the symptoms closely resemble those of

appendicitis. There is usually a history of past or present dysentery of varying severity. A palpable mass may ascend from the right iliac fossa toward the hepatic flexure and in some the thickened ascending colon may be palpated above the inflammatory swelling. The liver may also be enlarged and tender. If operated upon, the colon will be found irregularly thickened friable, and resembling damp blotting paper.

The appendix is commonly involved and its removal is disastrous because secondary perforation invariably follows. If the abdomen is opened the paracolic gutter should be drained and followed by specific medical therapy. If operation is not done the infection may resolve or form an abscess. The latter should be drained and appropriate medical therapy instituted. If specific therapy is not used phlegmonous ulceration will probably ensue.

The left colon is less commonly involved. Symptoms are essentially the same. Mortality from peritonitis is higher because of less tendency toward focalization. Treatment is the same as for the right side but the pouch of Douglas should be drained as soon as the diagnosis of pelvic peritonitis is established.

Catastrophic hemorrhage from the colon may occur in amebiasis. Most cases respond to repeated transfusions, penicillin, and emetine some may require surgical correction. The one case in the author's experience was controlled by ligation of the ileocolic artery which supplied the hemorrhaging area.

Amebic granuloma is rare, and may be mistaken for carcinoma.

Amebic hepatitis and liver abscess are early and late stages of infection of the liver. The first responds to emetine therapy while the latter usually does not, and therapy is a point in differential diagnosis. Amebic hepatitis exhibits every gradation from the intensely acute to the most chronic and insidious, being delayed for years after the initial infection. Liver enlargement, fever, leukocytosis, and diminution or loss of movement of the right diaphragm are characteristic in varying degrees of acute or chronic hepatitis. Jaundice is mild if present. Once the diagnosis is established, emetine therapy (1 gr. daily) should be administered for from 10 to 12 days. If suppuration is not present rapid cure will result. If symptoms do not disappear the liver should be aspirated by a systematic exploration with a medium sized trochar and cannula to a depth of 3 1/2 inches, and as many as 6 punctures may be made before pus is found. The cavity should be aspirated and filled with penicillin solution. Aspiration should be followed by a second course of emetine 10 days after the first course. Aspiration may have to be repeated. Abscesses are single or solitary in 70 per cent of the cases, they contain either a yellow or chocolate colored viscid material which is not offensive. Amebas may not be found but are usually present in scrapings from the abscess cavity wall.

FREDERICK C. HOBBS, M.D.

Fitzsalmans, J: Some Observations on Nonspecific Abdominal Lymphadenitis *N Zealand M J* 1946 45 248.

Because of an obvious general increase in interest in abdominal lymphadenitis and in an attempt to stimulate wider interest the author records the following observations

Sixty per cent of the cases occur between the ages of 6 and 16 and 91 per cent under the age of 26. The duration of symptoms varied widely from a few hours days weeks up to 6 months and even 3 years. The incidence of upper respiratory infection is no greater in the author's series of 300 cases than in the average population. Appendectomy was performed in 99 of 100 cases. The same number of cases had abdominal pain. The leucocytes ranged from 1,400 to 26,000. A slight relative lymphocytosis (from 50 to 60%) was very constantly observed. The author concludes, however that consideration of the total white cell count in the differential diagnosis is not only valueless but definitely misleading. The mesenteric and pre-aortic glands are enlarged and in 3 cases the iliac adenitis followed the vessels as far as Poupert's ligament but the femoral glands were not palpable in the groin and thigh.

The clinical features are pyrexia (in 100%) abdominal pain (in 99%) recurring for weeks months or years, and accompanied by nausea or vomiting and precipitated by motion of the abdominal contents waxy pallor fatigue underweight and under development for age. Muscular rigidity or guarding is the important differentiation from appendicitis. The author found that 6 per cent of the cases of primary lymphadenitis developed a true appendicitis

secondarily. He also states that this condition not infrequently causes dyspepsia and peptic ulcer and that it is a common cause for so-called post-appendectomy pain.

At operation these glands exhibit a purplish red blush on the surface of the mesentery. The total volume of enlarged glands is considered to be of prognostic value. The glands involve the mesentery and pre-aortic glands, right up to the diaphragm and in a few cases enlarged glands may be palpated in the lower part of the posterior cervical triangle which suggests that they are the extreme upper limits of a chain of enlarged glands extending from the lower abdomen to the neck.

Microscopic examination reveals chronic inflammatory change. No organism has been identified. The author presents a diagrammatic representation of the different grades of the condition from subclinical to diagnosable clinical levels.

The only important form of treatment is rest for periods of from 6 weeks up to 6 months. Benefit often credited to appendectomy in cases of so-called chronic appendicitis derives from the coincidental bed rest.

Separation of this condition from the conglomerate group of appendicitislike abdominal pains entails and necessitates some important changes. Since it has been included in all groups of cases described and looked upon as appendicitis it is obvious that the conception of true appendicitis must be revised. Practically all statistics relative to appendicitis include those of nonspecific lymphadenitis and are vitiated thereby and therefore they must be accepted with due reserve.

JOSEPH GASTEL, M.D.

GYNECOLOGY

UTERUS

Trainor, R., and Peace, V. S.: Carcinoma of the Cervix with Special Reference to Young Women (Il carcinoma del collo uterino in rapporto alla età, con particolare riferimento alle donne giovani) *Clin. esist.* 1945 47 129

The authors report a series of 669 cases of carcinoma of the cervix seen at their clinic during the years from 1936 to 1943. One patient the youngest in the series, was 14 years of age. The incidence of carcinoma of the cervix at other ages was as follows: 14 per cent of the patients were from 10 to 20 years of age; 3.5 per cent were 21 to 30 years; 21.9 per cent were 31 to 40 years; 56.95 per cent were 41 to 50 years; 27.95 per cent were 51 to 60 years; 8.5 per cent were 61 to 70 years; and 1.24 per cent were over 70 years of age.

Morphological typing of the 669 cases revealed that 8 per cent of the patients were of type 1, 74 per cent were of type 2, and 18 per cent were of type 3. Irrespective of age groups, the greatest number of patients were of type 2.

Menstrual periods were regular in the majority of patients although a form of hypermenorrhea was present in patients in the fourth, fifth and sixth decades of life. Twenty four of the patients were under 30 years of age. In 20 of these the menstrual period was regular. The flow was scant in 1 patient, in 3 patients the amount varied and in 1 patient there was intermenstrual bleeding. Of the total number of patients, 6.27 per cent were multiparas.

In 13.29 per cent of the 669 cases of carcinoma of the cervix, the symptoms appeared in less than 1 year after delivery. In 5.09 per cent symptoms appeared in from 1 to 2 years.

ARTHUR F. CIPOLLA, M.D.

Stefanelli, S.: A Rare Case of Hemoperitoneum (Raro caso di emoperitoneo) *Clin. esist.* 1946, 48 33.

The author enumerates the different causes of hemoperitoneum and states that hemoperitoneum caused by rupture of an ovarian follicle or of a corpus luteum is no longer a rarity. He reports and discusses a case of a large hemoperitoneum caused by rupture of a superficial vein of a large subserous fibroid, of which condition there are only 29 cases in the literature. In all of the 29 cases reported the ruptured vessel was located on the posterior surface of the uterus. The cause of the rupture was given as continuous friction over the sacral promontory although local edema necrosis and sudden violent abdominal contractions are also considered as etiological factors. In the author's case the ruptured vein was located on the lateral right side of the fibroma, and corroborated the clinical picture as given by Albrecht i.e. (1) the syndrome of acute

anemia with collapse (2) peritoneal reaction with muscle defense, (3) sharp sudden pain and (4) the presence of a fibromatous mass.

The author's case was that of an unmarried woman 45 years old with a negative history who in the last 2 years had noticed a mass in the hypogastric region which had gradually increased in size. During the night she suffered sharp abdominal pain, at first located in the lower quadrant and then gradually involving the upper abdomen. This was accompanied by nausea. The abdomen was tense and skin pale and rectally a hard mass was felt in the smaller pelvis. A diagnosis of fibroma twisted on its pedicle was made and a laparotomy was performed. This revealed a large hemoperitoneum, containing more than a liter of blood, which had been caused by rupture of a subserous vein located on the lateral right surface of a fibroma. A subtotal hysterectomy was done. The removed mass consisted of multiple fibromas with a large subserous vein, and weighed 1,050 gm.

The author attributes the diagnostic error to lack of evaluation of the anemia symptoms, and the cause of the vein rupture to the friction of the uterus on the sacral promontory.

JOSEPH M. A. PATE, M.D.

Accidia, D.: Statistical Data Obtained from the Perugia Obstetrical and Gynecological Clinic on Uterine Fibromyoma and Fibromatosis from Jan. 1, 1936 to Dec. 31, 1944 (Dati statistici e considerazioni sul materiale di fibromi e fibromatosis uterina nella Clinica Ostetrica e Ginecologica di Perugia dal gennaio 1936 al 31 dicembre 1944) *Fed. gyna.*, Genova, 1946 4175.

In a study of 715 cases of uterine fibromyoma and fibromatosis, it was found that an alteration of the menses, characterized by hyperpolymenorrhea, was present. An anatomical and pathological change in the ovaries in association with the fibromyoma was observed in 42 per cent of the cases, while in 56 cases other organs such as the appendix and salpinx were involved. The author states that uterine malformations, which are present in 1 per cent of the cases, do not seem to have any etiopathogenic connection with the neoplasm. In 1 per cent of the patients, tuberculosis associated with myoma was observed while fibromas in conjunction with pregnancy were present in 1.25 per cent.

A total of 595 surgical operations were performed and in 120 cases radium and roentgen therapy were used. Subtotal hysterectomy was done in 68 per cent of all cases, and was considered to be the treatment of choice, as carcinoma of the cervical stump was found in 1 of 3 cases (48%). Few complications have kept the morbidity low while 8 deaths constituted a 1.34 per cent mortality rate.

ARTHUR F. CIPOLLA, M.D.

De Moraes, A.: Uterine Choriocarcinoma (Córdocarcinoma do útero). *Rev. bras. cir.* 1946 15 197

A case of malignant chorioepithelioma (choriocarcinoma) occurring in a 23 year old white housewife was reported on October 16 1944. She was considered well and without evidence of metastases after extirpation of the adnexae and a subtotal hysterectomy on April 22 1944. She presented herself because of severe and rather continuous uterine bleeding. This followed the interruption of a pregnancy because of poor general health on December 4, 1943. A normal child living and well had been delivered on July 10, 1943 but her first pregnancy had been interrupted, presumably for the presence of a mole.

The red cell count was 2,000,000 and 250,000 units of gonadotropic hormone per liter were recovered from the urine on the date of operation. By May 12 this had reduced to 50,000 units. Frank's pregnancy test was negative in May and October 1944. Convalescence was uneventful except for a transient pulmonary complication.

Numerous photographs illustrating the gross and microscopic aspects of the specimen are appended and a discussion of the problem of benign and malignant moles, based on the literature, is presented.

HIRSH T. LANGSTON M.D.

Gordon, C. A. The Manchester Operation with Special Reference to Parturition and Complete Prolapse. A Report of 206 Cases. *Am. J. Obst.* 1946, 51 115.

In a series of 206 Manchester operations, there were 36 women of less than 40 years of age, 16 of whom were less than 35 years old. Parturition has been known to occur in 10 of these. In 5 of these cases, no details of labor are available, nor is the actual end result known except in 1 case in which prolapse recurred. The essential data of the other 5 cases are reviewed. Prolapse did not recur in any case.

The relative merits of the combined operative procedure of vaginal repair and abdominal uterine suspension and the Manchester operation during the reproductive period are compared. The author recommends the Manchester procedure. In the author's experience the operation has given excellent results in 62 cases of complete prolapse in which observation has continued for long periods of time.

EDWARD L. CORNELL, M.D.

EXTERNAL GENITALIA

Watson, B. P. and Gusberg, S. B.: Prevention and Treatment of Carcinoma of the Vulva. *Am. J. Obst.* 1946, 51 179.

Carcinoma of the vulva is one of the rarer gynecological lesions. Like carcinoma elsewhere, successful treatment depends very largely upon early diagnosis. An even more important factor is the recognition and treatment of conditions which predispose to the disease. To emphasize certain significant

correlations suggested from their experience, the authors report 30 cases which came under their observation.

The singular importance of the prophylaxis and early diagnosis in this disease is made obvious by the fact that the average time lapse from the onset of symptoms to the beginning of treatment in this group was three and three fourths years. The symptom of vulvar pruritus in middle-aged women is a significant one. Temporizing measures are unjustified in the face of premonitory lesions whose relation to cancer is evident. The authors believe that any irritated or ulcerated lesion which does not yield in a short time to simple therapy should be subjected to biopsy by free excision. Every leucoplakic area which causes constant itching and necessitates scratching for its relief—with consequent breaking or fissuring—should be excised. Treatment with ointments, hormones and roentgen irradiation has no place in such cases.

The operation of radical vulvectomy with bilateral dissection of the superficial inguino-femoral nodes is the procedure of choice. Wide local excision may be used, both for biopsy and for its therapeutic value in cases of low grade malignancy. Roentgen therapy does not appear to be of value. The gravity of prognosis with extension of the disease into the vagina is notable in this series of cases.

The authors are not as pessimistic concerning the general group of vulva carcinomas as are many observers. They believe that many patients can be cured especially by recognition of the early symptoms and the early use of radical surgical therapy.

EDWARD L. CORNELL, M.D.

MISCELLANEOUS

Grigler, C. M. Urological Complications following Operation for Imperforate Hymen. *J. Urol.* Balt., 1946, 58 111.

A 21 year old negroess had had an operation for the correction of an imperforate hymen. Two years later she was seen because of constant leakage of urinous fluid and dyspareunia. Examination revealed complete destruction of the entire urethra, the external and internal sphincters and the anterior two-thirds of the bladder trigone. A thorough urological examination showed an essentially normal upper urinary tract. It was apparent that the bladder had been the organ used for coitus and because of edema and inflammation the vaginal walls had almost coalesced.

Plastic reconstruction of the bladder and urethra was abandoned because of the extent of destruction but since it had become useful as a fairly satisfactory organ for coitus, declension was made to allow its function to remain as such, and to detour the urinary tract into the bowel.

The operation was done in three stages. The right ureter was transferred into the sigmoid by the Wharton technique, first, the left ureter later and finally the cervix into the bladder trigone area. The

urinary tract functioned adequately sphincter control was adequate, menstrual flow and dysmenorrhea improved and the dyspareunia was relieved.

Two years later the patient presented herself and inquired regarding the possibilities of being able to have children. Examination revealed the cervix, uterus, and tubes to be normal.

GEORGE BRADYURN M.D

Herrera R. G: Treatment of Vaginal Discharge (Tratamiento del flujo genital) *Bol Soc. obst gyn. B Aires* 1946, 15 90.

In the author's series of 804 cases of vaginal discharge he emphasizes the importance of making certain the presence of a discharge, its origin, composition and etiology.

A discharge which is due to salpinx involvement, such as suppurative processes and carcinoma, produces a flow which is yellow amber in color and occasionally contains tumor cells. The treatment is mainly surgical.

Carcinoma of the uterus produces a watery purulent, or mucous discharge which may contain tumor cells, while adenocarcinoma produces a white discharge benign basal adenoma and submucous myoma produce a serous discharge. Inflammatory endometritis caused by gonococcus, septic infection, or tuberculosis produces a purulent discharge, and if a cervical stenosis exists a pyometra results. The presence of foreign bodies in the uterus is also an etiological factor.

The treatment for malignant tumors is hysterectomy and for benign tumors, surgical extirpation. Inflammatory lesions are treated with sulfonamides and penicillin however the treatment of tuberculous lesions is aimed at the associated infection. Foreign bodies are removed, and if the leucorrhea persists, a dilatation and curettage is indicated. Senile endometritis is treated with radium.

One of the most frequent causes of vaginal discharge is the presence of cervical lesions. In some of the patients with vagosympathetic disturbances, there was a hypersecretion of the endocervical glands which responded favorably to atropine. Neoplastic lesions are treated with radium or by surgical removal. Cervical tears due to obstetrical deliveries are repaired. Sulfonamides and penicillin are useful in the treatment of gonococcal infections while chronic cervicitis may be treated with silver nitrate tampons and also cauterization, followed by the local use of sulfanilamide, and if the cervix becomes secondarily infected, douches are useful.

Vaginal discharge is dependent upon the change of pH, a disturbance of glycogenesis which is caused by ovarian hypersecretion and produces an environment for bacteria with resulting erosions and discharge. Normally the vaginal secretion is white of acid reaction, and a flora of vaginal organisms. A pathological discharge is yellow greenish yellow thick, and foamy, with an acid reaction.

Genital hypoplasia is caused by the effect on the ovaries of anemia, tuberculosis diabetes etc.,

and a white discharge occurs which at times contains pyogenic bacteria.

Other causes of vaginal discharge are passive congestion of the pelvic organs due to ovarian tumors, uterine tumors and retrodisplacements also foreign bodies such as pessaries, and chemical irritants such as quinine and alum.

The treatment of tumors and foreign bodies is removal, while ovarian insufficiency is treated with estrogens. Local treatment with silver nitrate, acid douches in some cases and general measures such as regulation of sexual relation, cleanliness, repair of perineal tears dilatation of a stenosed perineum, and exercise, fresh air and nourishing food are helpful.

Trichomonas vaginitis is characterized by a foamy whitish discharge, and an intense pruritis which is worse after menstruation. Identification of the organism confirms the diagnosis. Arsenical powder or silver picrate are used in the treatment of this condition.

Vulvovaginitis due to Monilia albicans produces burning and itching which is aggravated by touch, micturition, coitus, etc. The discharge is small in amount and acid. Erythematous or erosive lesions with white plaques in the vagina, on smear are of diagnostic value. These lesions are treated with sodium bicarbonate tampons and gentian violet.

Vaginitis due to diphtheria produces an abundant purulent discharge with a yellow white membrane on a red vaginal mucosa. Treatment is with serum.

ARTHUR F. CROUCH, M.D

Serdukov M. G: Results in the Treatment of Gynecologic and Obstetric Conditions with Bogomolts Antiretroviral Cytotoxic Serum (ACS) *Vrachesnoe Delo*, 1945, 25 51.

The material here reported consists of 435 gynecologic and obstetric cases. The treatment consisted of intracutaneous injections on the anterior aspect of the upper arm, the first course of 0.1 0.2 and 0.3, at 3 day intervals of Bogomolts' serum, to be followed at not less than a month's time by the second course of 0.2 0.3 0.5 and 0.7. This second course, with its higher dosages, was given when the patient's response to the first was weak, or when a more rapid response was desired. Following all of these injections (more than 300) not a single instance of complication or harmful effect was observed. The local reaction was a reddening and some swelling of the skin with perhaps a small blister formation or generalized itching.

The inflammatory diseases comprised 137 cases with such conditions as periparametritis adhesiva, periparasalpingo-oophoritis, metroendometritis, and drosalpinx, pyosalpinx, erosions, endocervicitis, and vulvovaginitis. Treatment of these cases with ACS resulted in the disappearance of pains, normalization of the menstrual cycles, and resolution of the infiltrative processes. In this group 25 per cent of the women were sterile however following treatment with ACS 8 per cent became pregnant. There were 41 cases of endocrinopathy with infantile atrophic

conditions, including conical cervix, infantile under development of the uterus and absent or scant menses. In this group the treatment with ACS had been preceded without much result, by organo-therapy diathermy and massage. Sixty per cent of these patients were without children and following treatment with ACS 6 became pregnant. In 15 there was a correction of the oligomenorrhea or amenorrhea with increase in the size of the uterus and its blood supply.

The third group into which the author divides his material consisted of 40 patients with fibrotic metropathias and subserous fibromyomas, the tumors varying in size from a billiard ball to that of two fists. Following treatment with ACS there was shrinking of the tumor mass when adhesions and inflammatory process were present the serum in this wise contributing toward the patient's readiness for operation. Menstrual disturbances were corrected.

The fourth group included 77 cases of vegetative neuroses, endocrine and climacteric disturbances and high blood pressure. In these patients the climacteric symptoms had lasted from 1 to 20 years and included the usual manifestations such as hot flashes, sweating, headaches, loss of memory and strength, sleeplessness, palpitation of the heart and idea impulses. Blood pressures were as high as 250/180 and 280/200. In this group the results of ACS treatment were most striking. In 90 per cent there was a complete relief from the menopausal syndrome. The blood pressures went down rapidly to normal and remained down.

In the fifth group there were 15 toxemias of pregnancy. ACS relieved the symptoms in every instance and the pregnancy progressed to the birth of a normal child. Results were quite as striking in the group of 25 mothers with poorly developed breasts and hypogalactia. Following the second injection a marked increase in both the size of the breast and in the milk flow developed. The results were attributed both to a local hyperemia and to stimulation of function of the milk producing epithelium of the mammary glands.

The seventh group included 25 patients who had either been operated for cancer of the cervix, or were harboring precancerous lesions and who complained of pain, weakness, depression and loss of weight and capacity for work. Treatment with ACS brought about not only amelioration of the subjective symptoms, healing of the ulcers and erosions, and softening down of the deforming scars from previous operation but caused the previously ineffective medical measures (manganese and iodides) to become effective.

Finally the eighth group included 70 patients with a variety of complaints complicating the gynecological ailment, such as gastric ulcers, hyperacid gastric catarrh (20 patients), hepatitis, stomatitis, and eczema. Practically all these patients evidenced remarkable response to ACS.

In the vast majority of this whole material in addition to the more specific ameliorative or curative

effects from ACS the patients showed increase in weight and strength, and improvement in appetite and ability to sleep. They would develop a cheerful hopeful life outlook and the general laboratory picture would improve with an increase in hemoglobin, red cell count and relative and absolute numbers of monocytes, and there was a shortening of the clotting and bleeding time of the blood and in the time of resorption of test dyes (unblocking of the reticulo-endothelial system).

As regards the ultimate results the author maintains that the maximal effects in 50 per cent of the cases last from a half year to 1 or 2 years. In the event of a recurrence of the complaints the repetition of the ACS medication will reconstitute the original effects of the treatment. JOHN W. BURNHAM, M.D.

Silvestroni E. Tamburello S. and Bianco I.: The Influence of Some Sexual Hormones and of Cholesterol in the Productive Phenomena in the Uterus and in the Mammary Gland (Influenza di alcuni ormoni sessuali e della colesterina sui fenomeni produttivi nell'utero e nella mammella). *Tumori Milano* 1941 27 330.

The authors conducted a series of experiments to determine whether or not some hormones especially the estrogens, cause malignant tumors. Fifty adult rats were subjected to oophorectomy. Twenty-seven days after the surgical procedure the rats were divided in five groups and for a long period of time were given injections of estrogen, progesterone, testosterone propionate and cholesterol alone or combined. Autopsies were carried out and histological changes in the uterus and breast were studied.

The authors are of the opinion that with the continued injection of folliculin the hyperplastic and metaplastic processes in the uterus and mammary gland recede and that malignancy does not occur. Their conclusions differ from those of Bonser, Stuckland Connal and Geschickter who claim that the estrogens are carcinogenic even in animals refractory to such preparations. The results of Geschickter therefore must be further confirmed. The authors are not alone in their view because the results obtained by Livraga (1937), Korenchevsky and Hall (1938), Einge (1939), and Silvestroni (1930) have been the same. On the other hand Gardner Allen Smith and Strong and McEwen (1938-1939) have observed the appearance of uterine cancer after the administration of estrogens. They conclude that while the sexual hormones may start a process capable of causing malignant changes in an hereditary substratum predisposed to cancer still it is very difficult to cause cancer by estrogenic stimulation alone.

Testosterone is believed to have an antineoplastic property instead of a carcinogenic one. This view is held by Lacassagne, Raynaud, Nathanson and Andervont. Lacassagne believes that injections of large doses of testosterone given early in life prevent cancer by bringing to a standstill the development of the mammary gland. This corresponds to the early

castration of Lathrop and Loeb (1916) "Microscopical examination of the breast (Lacassagne & Raynaud 1939) of some animals has demonstrated that large injections of testosterone started shortly after birth stop the development of the mammary gland in female rats the breast of these animals consisting of a rare primary duct with the cell at complete rest. The architecture is identical with the histological findings of the breast of the normal adult male rat." In their series the authors observe that in castrated female rats (therefore deprived of ovarian function) the administration of testosterone causes a great proliferation of the epithelial and connective tissue rather than mammary atrophy, the process continuing in some animals beyond 60 days.

They conclude therefore, that the function of testosterone is proliferative rather than oncogenic. Progesterone given in large doses (up to 7 mgm of progesterone weekly) does not inhibit but enhances the hyperplastic and metaplastic processes induced in the uterus by the folliculin and if the injections are continued a regression of the process takes place. The animals treated with cholesterol and folliculin, and cholesterol and testosterone appeared to be in a better nutritional state and lived much longer than the animals treated with folliculin or testosterone alone. Histologically the uterus and mammary gland showed a more healthy condition of the cells rather than an indication of malignant changes.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

De la Puente Campano L.: Interstitial Pregnancy (Embarazo Intersticial) *Rev. esp. obst. 1946* 3 394.

The author reports a case of interstitial pregnancy in a 35 year old woman. The fetus was located in the right interstitial portion of the uterus. Following rupture, the patient was operated upon with an uneventful postoperative course.

A detailed discussion of interstitial pregnancy is presented

WILLIAM E. RICKETTS, M.D.

Robertson, G. G.: Nausea and Vomiting of Pregnancy: A Study in Psychosomatic and Social Medicine *Lancet* Lond. 1946 1 336

The author first became interested in this problem through his discovery of a dyspeptic syndrome in nonpregnant women. The symptoms of this syndrome include dyspepsia and cessation of sexual interest soon after marriage. The symptoms usually become manifest in the late evening or at the week end when the threat of coitus is strongest. Attacks of nausea and vomiting occurred frequently. The patients came to dread coitus and developed signs of anxiety. These patients were not psychoneurotic.

This syndrome was first recognized in 1938 by the author and he named it 'rejection dyspepsia.' By 1943 after studying many women with this syndrome it became evident that these women invariably had a history of protracted or severe nausea and vomiting during their pregnancies.

As a result of these observations the theory is postulated that nausea and vomiting of pregnancy is related to frigidity. Further study revealed that many of these patients displayed a very strong attachment to their mothers or were very dependent on them.

The triad of symptoms in this syndrome therefore included dyspepsia, mother attachment and sexual frigidity. These symptoms first appear before marriage or soon after marriage.

The author investigated 100 consecutive pregnant women: 57 had nausea and vomiting and 43 had none. The latter group was considered as controls. Of the 57 patients 6 had a history of previous dyspepsia against none of the controls. 20 of the 57 patients showed undue mother attachment against 4 of the 43 controls, and 40 of the 57 patients showed disturbed sexual functioning against 4 of the 43 controls. Sex is therefore considered an important factor in the etiology of nausea and vomiting of pregnancy.

The mechanism whereby a pregnant woman's aliment takes the form of nausea and vomiting is described as follows. A psychosomatic approach suggests that the nausea and vomiting may represent the physical expression of an emotional constellation

in which disgust is predominant. It also suggests that the biochemical changes associated with pregnancy probably lower the threshold of the physical expression of a latent or subconscious disgust hence when the ovum dies or the fetus is removed, the threshold to physical expression is again raised and vomiting ceases. In other words, pregnancy serves as a trigger. These suggestions are consistent with the absence of any proved toxin, the probable change of hormonal secretions accompanying subconscious emotional activity (as well as pregnancy), and the absence of any specific pathological lesion.

In summary the author states that he has given a clinical and statistical investigation of the nausea and vomiting of pregnancy, demonstrating that the syndrome may be the physiological expression of an underlying emotional state which may be equated with that of disgust. The etiological factors involved are disturbed coital function, undue mother attachment, and a history of previous dyspepsia. Relevant factors in the life situation are frequency of undared coitus and the physical propinquity of the mother. Therapy is suggested along these lines.

HARRY FIELDS, M.D.

Vara, P. and Haiminen E.: On Fetal Electrocardiography *Acta obst. gyn. scand.* 1946 56 249

The authors believe that the only available methods of determining the condition of the fetus namely palpation and auscultation are inadequate and, therefore, they attempt to use the electrocardiograph in further studies along these lines.

They attempt to answer the following questions:

1. Is the fetus alive or not?
2. Is there a single or a multiple pregnancy involved?
3. What is the presentation or position of the fetus at any given time?
4. Is there anything pathological to be observed in the fetal heart action?
5. Can the effect of occurrences incidental to pregnancy or delivery (such as labor pains, rise in mother's temperature, drug reactions) be observed in the heart action of the fetus?
6. Can fetal electrocardiography be used as a reliable method of early diagnosis of pregnancy?

Cramer in 1906 reported the first successful examination of fetal heart action with the aid of an electrocardiograph tracing. He used abdomen-vagina and abdomen-rectum couplings. Strassman and Mussey (1938) were able to determine whether the fetus was alive or dead in 52 cases and thought they could determine the position of the fetus. They used upper extremity and one thigh coupling.

Spångberg (1942) in 15 of 17 cases observed positive results with the abdominal application of the electrocardiograph. In the 2 negative cases, 1 fetus was dead and 1 alive. Using the abdominal

application, Bortor (1943) recorded a fetal electrocardiograph 35 days before delivery in 51 patients. Application to the navel and symphysis has given results to Haynal and Kellner (1924), Mackawa and Toyoshima (1930), Yashura (1931) and Bell (1938).

According to the literature available to the authors only Puts and Ulrich (1941) and Spøndergaard succeeded in recording fetal electrocardiograms during the early stages of pregnancy.

In the diagnosis of double pregnancy the electrocardiograph was successfully used by Dressler, Morris and Moskowitz, Spøndergaard and Bortor and others. The literature they say is meager because only positive results are recorded.

In 1945 the authors began work with an old fashioned Siemens electrocardiograph but later a more modern model made by the same company with amplifiers was added in the form of a 20-power amplifying tube and a rapidly revolving cassette. The patient was kept inside a grounded wire net.

The authors used several couplings, namely upper extremity and thigh, vagina fundus, and another method in which a flexible rod was run up between the membranes and the uterus and the vagina. They report the method caused the patients no trouble, but it was inconvenient, did not give good results, and was not simple enough for practical clinical work. The vaginal method was inconvenient also.

In the method of choice one electrode was applied to the symphysis and one on either side of the fundus, and in early pregnancy (third and fourth month) application was made from the abdomen to the torso.

Thirty cases were studied during different stages of pregnancy—5 cases in the tenth month, 10 cases in the ninth, 4 in the eighth, 3 in the seventh, 2 in the sixth, 3 in the fifth, 1 in the fourth and 1 in the third. Positive results were obtained if the fetus was alive. In 1 case no waves appeared during the fifth month, and induction later revealed a dead and macerated fetus.

The authors believe that they can tell whether the fetus is alive or dead, but they could not determine position, presentation or attitude. They believe it is possibly an early method of diagnosing pregnancy as it was positive in 1 case at the 3rd month. The fetal and maternal heart rates were proved to be independent.

BYRONO F. HANKEK, M.D.

Portes L., and Granjon, A.: The Presentations in Twin Deliveries (Les présentations au cours des accouchements gemellaires). *Gyn. obs. Par* 1946 45: 59.

The authors present a statistical analysis of a series of 1,000 twin deliveries (2,000 babies) according to their presentations. Abnormal presentations, such as occipitoposterior, forehead, face breech, and shoulder presentation occur more frequently in the second than in the first twin. In order to avoid the danger and high mortality of these pathological pre-

sentations, the authors suggest the performance of a prophylactic internal version in the second twin in all such cases.

WILLIAM M. SORELL, M.D.

LABOR AND ITS COMPLICATIONS

Guyer H. B. and Heaton, C. E.: The Fetal Risk in Breech Delivery. *Am. J. Obs.*, 1946, 51: 351.

Statistics from many clinics over a long period of time have shown a high fetal mortality rate in breech as compared to vertex delivery. Despite refinements in technique, there has been no significant improvement since Holland in 1932, showed that 75 per cent of the term fetal deaths in breech deliveries are due to laceration of the tentorium cerebelli with subdural hemorrhage. Since no standard has been accepted for the exclusion of complicating factors, mortality rates of different authors have varied considerably, and there has been no agreement as to the amount of fetal risk involved in breech delivery itself.

To determine this fetal risk, the authors studied 1,708 cases of primary breech delivery occurring at the Bellevue Hospital of New York between 1934 and 1944. There were 220 stillbirths and neonatal deaths, or a gross fetal mortality rate of 31 per cent.

Breech delivery with complicating conditions, such as nonviable infants, premature infants, twins, prolapse of the cord, maceration of the fetus, congenital defects, pre-eclampsia and eclampsia, premature separation of the placenta, placenta previa, hemorrhagic disease of the newborn and lacerations, were then excluded. There remained 131 normal breech deliveries with 16 fetal deaths, giving a corrected fetal mortality rate of 4.5 per cent. Of the 16 fetal deaths, 11 or 69 per cent, showed evidence of birth injury at autopsy. Of the 11 cases, 8, or 73 per cent, showed evidence of slight to moderate degree of disproportion between fetus and pelvis.

Every primipara, and any multipara, with a history of difficult or premature deliveries, in whom a breech presentation is found that cannot be changed by external version should be carefully studied both clinically and radiologically. The size of the fetus should be estimated with care. On the basis of these studies, if slight to moderate disproportion is found to exist, an elective or early cesarean section is indicated.

JOHN R. WOOT, M.D.

Dieckmann W. J.: Fetal Mortality in Breech Delivery. *Am. J. Obs.*, 1946, 51: 349.

Breech delivery according to reports, still has a fetal mortality ranging from 3.8 to 59.0 per cent. The average gross mortality is 7.7 per cent, corrected to 4.2 per cent for term fetuses on 5 maternity services. The mortality in premature deliveries is over 25 per cent.

Fetal deaths as a result of breech delivery are due principally to prematurity, intracranial injury, asphyxia, and visceral injuries. Twenty-three per cent of the premature infants showed no demonstrable cause of death at autopsy and although anesthetic drugs were used infrequently anesthetics were used

at delivery. The author believes that women in premature labor should have no analgesic drug and should have a minimal amount of anesthesia at delivery the latter if possible being conducted under local anesthesia.

External version should be attempted repeatedly after the thirty-second week. No undue force and no anesthetics are to be used.

Dieckmann presents a systematic outline for the management of breech delivery but insists that each case be evaluated individually. First of all elective cesarean section should be performed in all patients in whom the pelvis is contracted (or borderline) with a large baby. Primiparas who are 35 years and older with large babies unless labor progresses normally should have a cesarean section. Labor should be allowed to progress normally but a final decision as to management should be made after 6 to 18 hours of labor and/or ruptured membranes. Large doses of analgesic drugs should only be given when labor is progressing normally.

In a test of labor in a breech delivery one is to be guided primarily by the length of time it takes for the cervix to dilate. When progress is slow and vaginal delivery is preferred, the author suggests the use of a large (9 to 11 cm.) Voorhees bag inserted into the vagina.

Dieckmann believes that although one should not interfere with normal progress the prompt recognition of abnormal labor especially when there is no progress in the presence of a completely dilatable cervix, will do much to lower fetal mortality. Delivery must always be accomplished when there is no descent for 1 hour in the presence of a completely dilatable cervix. Deep surgical anesthesia best with drop ether is a distinct aid to delivery. The delivery must be slow and deliberate. A deep episiotomy should be performed. The Potter technique for the delivery of the shoulders will prevent complications. The head should be delivered with the aid of the Celsus-Weigand Martin maneuver or the combined with forceps. After delivery the vagina, cervix, and lower uterine segment should be examined for laceration and ruptures.

JOHN R. WOLFE, M.D.

MISCELLANEOUS

André-Thomas: Obstetrical Paralysis of the Upper Limb (*Les paralysies obstétricales du membre supérieur*). *Gyn. et Obst.*, 1946 45 76 175.

Birth palsies of the arm may be of either central or peripheral origin. The former may be caused by prolonged hard labor by the application of forceps or by the cord which may encircle the neck and cause strangulation. The baby is born asphyctic and convulsions are frequent. Periphereal paralysis and contraction of the brachial plexus seem to be caused more often by forceful traction on the head and neck than by pressure of forceps in any case faulty or brutal manipulations, e.g. in attempting to bring down the arm are the causative factors in most cases.

The author reports 40 personal cases and discusses more than 1,000 cases recorded in the literature.

By far the most frequently encountered obstetrical paralysis is the superior type of Erb-Duchenne. The involved muscles are the deltoid, the supraspinatus and infraspinatus, the biceps brachialis, the supinator longus and the extensors of the hand. The limb hangs down parallel to the trunk, the shoulder is drooped, the hand is in pronation and internal rotation and the fingers are flexed tightly in the palm. Since the triceps is spared and hypertonic due to the lack of antagonists the forearm can be extended farther on the involved than on the normal side where as flexion on the paralyzed side is limited as compared with the normal side.

A number of manipulations to determine the degree of paralysis of the individual muscles are described. The symptoms are not limited to the arm in all cases, but include the movements of the head and neck. The head can be passively rotated farther to the normal side than to the affected side and the chin can be approached closer on the normal shoulder than on the paralyzed side. The radial reflex is lost whereas the tricipital reflex is increased. The sensibility is normal in most cases. No edema or hematoma in the region of the brachial plexus was ever found.

As to the prognosis about half of the cases clear up completely within periods from 3 weeks to 2 or 3 years. It is difficult to establish a correct prognosis during the first few weeks or months. Only after a period of about 3 months will the different signs especially the electrical reactions and the radial reflex, help to establish the prognosis. About half of the patients retain some degree of paralysis permanently.

In older children, the picture is very different from the syndrome in the newborn and in the infant the shoulder is hyperextended due to hypertony of the trapezius the arm is less abducted and the elbow more flexed than in the infant. In most of these cases the deltoid and the flexors of the forearm have regained some of their function whereas the position of internal rotation and pronation persists. Complete paralysis involving the fifth cervical and the first dorsal roots is rare and occurred in only 2 per cent of the recorded cases. In most cases the sensibility is involved too the anesthesia including the hand forearm and elbow region. The tendon reflexes are abolished. Frequently the Horner syndrome (miosis, endophthalmitis and narrowing of the palpebral fissure) is present indicating involvement of the first dorsal root. Vascular disturbances and sympathetic symptoms are frequent, such as lowering of the skin temperature and absence of sweat secretion. In the later course of the condition atrophy of the bones and muscles is more pronounced.

The inferior type of Klumpke. Involving the seventh and eighth dorsal nerves, is also very rare. All the small muscles of the hand are involved (the thenar hypothesis the lumbricals and interossei). The only possible movement is extension of the first phalanx. The Horner syndrome is usually present

and very pronounced. Disturbances of sensibility involve the third and fourth finger and the medial aspect of the forearm. Nothing is said of the prognosis of this type.

Bilateral palsies are rare too they seem to occur especially in breech presentations due to the pressure of the fingers of the obstetrician on the cervical and supraclavicular region. The superior type of paralysis is predominant in bilateral palsies. The paralysis may clear up completely within weeks or months however permanent bilateral palsies have been observed too.

The diagnosis of the plexus paralysis seldom presents any difficulties. The condition has to be differentiated from fractures and dislocations of the clavicle and humerus. Paralysis of cerebral origin almost always is found to involve the leg as well as the arm.

The author discusses in detail the pathology and pathogenesis of obstetrical paralysis. Because of the scarcity of pathological reports, little is known as yet about these questions. In the rare cases in which pathological studies were possible, the findings were, hemorrhages near or in the plexus, stretching and tearing of nerve fibers, and rupture of the spinal roots above or below the spinal ganglia, which occurred in several cases sometimes the plexus was caught in cicatricial tissue. Different causes may be responsible. There are many cases on record in which the paralysis occurred in spontaneous delivery either after prolonged hard labor or after precipitation. In most cases however obstetrical maneuvers are held responsible. The paralysis occurs more frequently in breech than in cephalic presentation considering the much higher incidence of cephalic delivery. As to the causing mechanism, it would seem, from experiments, that traction on the head and

neck plays a more important role than pressure. If the traction is exerted from the head downward, the superior roots are affected most in the opposite case, as in breech extractions the inferior roots are injured first. However these experiments do not explain why the sensitivity is normal in most cases of upper paralysis. As the experiments were done on cadavers, many factors are quite different from the condition in the living and, on the whole, it seems that at present very little is known as to just what happens in plexus paralysis, especially just where, in the course from the spinal medulla to the nerve, most lesions occur.

As to therapy it appears doubtful if the customary electro- and physiotherapy are effective and useful. Some authors maintain that the galvanic treatment may cause contractures and retractions of muscles. Early surgery (dissection of scar tissue pressing on the nerves) has not proved effective. A great number of authors recommend orthopedic appliances which fix the arm in abduction of 90° the elbow is rotated externally the forearm is flexed at a right angle and supinated. The author doubts whether much can be accomplished by these inconvenient appliances. Much more beneficial is corrective surgery which, however, should not be done before the age of 4 to 5 years. Many operations have been suggested, such as tenotomies, resection or transplantation of muscles, etc. The author considers as the ideal operation in older children the osteotomy of the humerus in its upper or lower third, followed by anterior rotation of the distal fragment. This operation corrects the vicious pronation and inward rotation of the forearm and makes the hands more useful, it enables the children to write and to use the fork and spoon with the paralyzed arm.

WERNER M. SCHULTZ, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Esperen, T., and Dahl Iversen E: The Clinical Picture and Treatment of Pheochromocytomas of the Suprarenal. *Acta chir scand* 1946 94 272

The authors describe the development of the marrow cells and the different tumor forms corresponding to the different stages of development. Up to the present time about 120 cases of intra-adrenal pheochromocytoma and probably only 15 cases of true extra-adrenal pheochromocytoma have been reported, most of them necropsy findings. The pathogenesis, symptomatology, diagnosis and differential diagnosis are reviewed, and the results of surgical treatment are mentioned. The operative mortality is high. Of 46 patients operated on (the authors included) for both extra and intra-adrenal pheochromocytomas 12 (26 per cent) died.

The authors relate 2 cases of their own.

The first patient was a man 49 years of age with paroxysmal hypertension due to a benign pheochromocytoma of the right adrenal. The blood chromocytoma was found to be increased from four and one-half to five times during attacks. Treatment with methylthiouracil resulted in complete disappearance of the attacks. The tumor, which weighed about 1400 grams, was removed with good result.

The second patient was a boy 10 years of age with permanent hypertension due to a pheochromocytoma. Operation through a left lumbar incision failed to demonstrate the tumor. The patient died 6 hours after the exploratory intervention probably from shock. At autopsy a malignant pheochromocytoma (4.5 by 3 by 2 cm.) was found situated in front of the large vessels connected by a small pedicle with the lower mesial angle of the left adrenal gland.

The authors believe that the only treatment in these cases is extirpation as soon as the diagnosis has been established and the patient's condition permits. They recommend preoperative treatment prior to extirpation of the adrenal gland. The reports in the literature as well as their own experiences lead the authors to believe that there may be reason to consider whether the best principle might not be to choose the abdominal approach in all cases of pheochromocytoma, irrespective of the size of the tumor and even when the location is known. When the tumor is large, they recommend Shipley's incision. One of the dangers of surgical intervention is shock, which is counteracted by pericortin blood transfusion and, if necessary the administration of adrenalin.

JOHN A. LOFF, M.D.

Florence, T. J., Howland, W. S., and Weens H. S.: Intravenous Urography in Acute Renal Colic. *J Urol*, 1946, 56 214

The authors studied a group of patients with acute renal colic by means of intravenous urography using

intravenous diodrast solution preceded by pantopon and atropine. In 10 cases a nephrogram (opacification of the kidney shadow after intravenous administration of contrast medium) was obtained.

The authors are impressed by the frequency of the phenomenon, and the infrequent mention of it in standard urology texts. They explain it as follows:

In complete ureteral obstruction the intrarenal pressure gradually rises to a level at which glomerular filtration is suppressed. The tubular epithelium function and may excrete diodrast which accumulates in the tubular apparatus leading to a diffuse opacification of the renal shadow on intravenous urography as soon as the obstruction is relieved. The contrast medium passes readily from the tubules into the kidney pelvis and the kidney shadow returns to normal density. Nephrograms were obtained in cases of stricture as well as in calculous ureteral obstruction. In a survey of 23 cases, roentgenograms showed opaque calculi in only 11 but intravenous urography demonstrated a calculous or a ureteral obstruction in all but 1 case. In 5 of these cases blockage was so complete as to produce a nephrogram.

The principal advantage of intravenous urography is that it facilitates the early recognition of urinary tract obstruction and the differential diagnosis of acute abdominal conditions. The authors stress the opacification of the kidney (nephrogram) as a sign of ureteral blockage.

DAVID ROSENBLUM, M.D.

Nesbit R. M., and Adams, F. M.: Wilms Tumor. *J Pediatr* S. Louis, 1946 29 295

The authors report a series of 16 cases of Wilms tumor. The patients were treated at the University Hospital Ann Arbor Michigan during the 9 year period from Jan. 1, 1934 to Jan. 1, 1943.

In 3 of the cases the tumors did not entirely conform with the usual pathological picture. Two of them were diagnosed as adenocarcinomas. One of which might have been a variant of a Wilms tumor. In the third case the tumor was diagnosed as a teratoma. It is believed that these 3 cases should be included in this series for clinically the condition was indistinguishable from a typical Wilms tumor.

The diagnosis of a Wilms tumor is not difficult for the physician to make. In a child, usually under 5 years of age with a history of progressive enlargement of the abdomen and with the finding on physical examination of a firm, nontender smooth, or finely nodular mass which usually fills one-half of the abdomen the presumptive diagnosis of a Wilms tumor can quickly be made. The second most common abdominal tumor in childhood and one which gives the most difficulty in the differential diagnosis is the sympathoblastoma or neuroblastoma, of the

The diagnosis is usually established by pyelography. Subcutaneous or intravenous injection of diodrast is quite simple and in many instances satisfactory results are obtained. If results are not successful, and if it is considered that pyelograms are necessary for the diagnosis, the retrograde method is used.

The so-called characteristic pyelographic changes seen in a Wilm's tumor are (1) distortion of the renal pelvis and calices, (2) displacement of the renal pelvis upward, downward, or lateralward depending on the position of the tumor within the kidney and (3) failure of visualization of the kidney pelvis. However it should be remembered that these described changes are not absolutely diagnostic, but merely suggestive of a Wilm's tumor. When no contrast medium can be seen in the pelvis or calices on the affected side the diagnostician must think of hydronephrosis as well as neoplasm.

A procedure formerly used as an aid in the diagnosis, but now thrown into discard is that of aspiration biopsy. It is believed that the risk of setting malignant cells free into the peritoneal cavity as metastatic sites does not warrant this procedure being carried out.

The series of cases is small and the fact that the treatment has varied from patient to patient makes it impossible to draw any conclusions as to what is the proper form of therapy. However in recent years the following policy has been adopted in treating these patients: preoperative irradiation is reserved for those cases in which the tumor is so large that operative removal would be technically very difficult thus minimizing the chances for survival. Postoperative irradiation was formerly employed only in those patients in whom regional metastases were grossly evident at the time of operation, or if a pathological study of the regional lymph nodes showed metastatic involvement. However now the policy of giving all patients postoperative irradiation has been adopted. This change in policy has been made because 3 of the 8 living patients very definitely owe their survival to irradiation therapy. As such, it is now felt that every patient should have the benefit of possible lifesaving postoperative irradiation.

In summary the authors state that the diagnosis of a Wilm's tumor was confirmed by pathological study in all cases. Of the 16 children 8 are still living for a period of time ranging from 3½ to 11½ years since the institution of treatment.

It is of particular interest to note that of the 8 children apparently cured only 7 had nephrectomies. The survivor who was not operated upon was first seen here in 1933 at the age of 14 months with idiopathic hydrocephalus. She was next seen in March 1935 with the new complaint of abdominal enlargement, the hydrocephalus had since become arrested. Physical examination at that time revealed a huge finely nodular mass occupying the entire right half of the abdomen. An intravenous pyelogram failed to show any visualization of the

right renal pelvis. An aspiration punch biopsy was sufficiently diagnostic to make a clear-cut diagnosis of Wilm's tumor. Chest x-rays showed a right pleural effusion interpreted as being due to metastatic lesions in the lung. Therefore the tumor was considered to be inoperable and the patient was given palliative irradiation therapy over the right abdomen and right chest. She received a total of 1,800 roentgens in divided doses over a period of 2 weeks time. She was not seen again until 1939, when an examination revealed no evidence of any abdominal mass and x-rays showed that the chest was clear. She was last examined in October 1945 and was free from evidences of neoplasm at that time, 10 years following the original diagnosis.

Twelve of the 16 patients had nephrectomies. Seven of these children have lived long enough post-operatively to be considered cured by the standards set up by most authors.

Two of the patients, at operation, had gross evidence of retroperitoneal extension of the tumor. They were given postoperative irradiation, and the fact that they are still living shows adequately the value of this procedure.

With one exception all of the 5 patients who had nephrectomies and have since died showed evidences of metastases within 6 months postoperatively.

Operation was denied 4 of the 16 patients, either because of pulmonary metastases, or because they were in such poor condition that they were considered hopeless operative risks.

JOSEPH A. LOCK, M.D.

Everett, H. S., and Wayburn, G. J.: A Unique Case of Submucosal Epithelial Nests in the Ureter and Renal Pelvis. *J. Urol. Balt.*, 1945, 56, 31.

The authors report the case of a 55 year old colored female patient who suffered with gross hematuria and was finally subjected to a left nephrectomy and partial ureterectomy which demonstrated grossly a normal kidney and upper ureter. However upon microscopic study of the upper ureter it was found to contain numerous solid nests of epithelial cells which penetrated into the submucosal connective tissue and muscularis, and in one area the lumen had eroded into the lumen, revealing free cells and suggesting early squamous cell carcinoma.

In 1893 von Brunn found such a lesion in the upper ureter and bladder. It was thought by this authority to be due to an infolding of the epithelium. Since the initial report of this condition by von Brunn, lesions of this character have been described and this origin is still obscure. Moore, in a study of 125 necropsies, found these inclusion bodies present in 103 individuals. Von Limbeck suggested that a central liquefaction of these inclusions produced a cystic condition i.e. cystitis cystica, ureteritis cystica etc.

Patch and Rhea believed these cell nests in the bladder to be the forerunners of cystic and glandular conditions which in turn lead to adenocarcinoma. Stirling and Ash uphold this opinion, and Bothe only

last year reported his experience in finding benign cell nests in one portion of the ureter or pelvis and gross carcinoma in another. This leads to the ever important step of removing the entire ureter in carcinoma of the renal pelvis to prevent its not infrequent recurrence in the stump.

ROBERT LICH, JR., M.D.

BLADDER, URETHRA, AND PENIS

Coe, F. O., and Arthur P. S.: A New Medium for Cystourethrography. *Am. J. Roentg.*, 1946, 56, 362.

Since 1930 the authors have used a medium called viscorayopake for cystourethrography. This is an aqueous solution with approximately 50 per cent organic iodine compound and 3 per cent polyvinyl alcohol. It fulfills all the necessary requirements of a good contrast medium for cystourethrography: namely maximum opacity, minimum irritation, homogeneous nature, suitable viscosity, and it is not necessary to remove the dye from the bladder and urethra after instillation as it is miscible with urine. This preparation has been used in all types of cases, including traumatic rupture of the urethra and there have been no unusual reactions.

The following is a brief description of the technique employed. The only equipment necessary is a 30 c.c. syringe with 5 cm. of soft rubber catheter firmly attached to the tip as an adapter.

A plain roentgenogram of the abdomen is taken first. The bladder is emptied of urine. The patient is placed in the right anterior oblique position (i.e. with the left hip slightly elevated by use of a sand bag under the left hip. The right thigh is flexed and the left extended. The tube is centered directly over the symphysis pubis and a technique making use of the Potter Bucky diaphragm is employed. The operator then inserts the soft rubber catheter adapter into the urethra with the right hand, forcibly extends the penis with the left hand and at the same time exerts considerable pressure about the adapter to prevent the dye from regurgitating. Twenty cubic centimeters of the dye are slowly but steadily injected; the operator's hands are protected with $\frac{3}{4}$ inch of lead plate and the first exposure of a stereo pair is made. It is important to keep constant pressure on the plunger of the syringe at all times. While the plate is being changed the remaining 10 c.c. are injected and the second exposure is made. The anteroposterior roentgenogram is made by immediately placing the patient in the supine position and continuing the pressure on the plunger of the syringe. It is not necessary to remove the dye mechanically.

JOHN A. LOZZ, M.D.

Vermooten, V.: Rupture of the Urethra: A New Diagnostic Sign. *J. Urol.*, Balt., 1946, 56, 513.

Injury to the urethra or bladder commonly occurs with crushing wounds to the lower half of the abdomen. The extent of the injury is often difficult to determine. There are numerous diagnostic aids which

Fig. 1 (Vermooten) Showing how as examining finger in contact with apex of prostate, is pushed upward, prostate is also readily pushed up, indicating a complete rupture of the urethra.

include rectal palpation. Injection of a radio-opaque contrast medium through the urethra for delineation of extravasated urine and cystoscopic examination. The author strongly condemns the practice of injecting a known quantity of sterile fluid through a urethral catheter and measuring its return; such practice, he states, is not only harmful but can only yield wrong information.

The most common type of urethral injury in males is a complete rupture at the level of the apex of the prostate (i.e. just above the urogenital diaphragm). In such a case, the pubococcygeus muscle which forms the anterior border of the levator ani muscle contracts and elevates the prostate, this process being aided by the accumulation of blood in the space of Retzius. A wide separation results between the prostate and membranous urethra which with subsequent scar formation will make later attempts to excise the scar and reanastomose the urethra impossible or at best will produce a persistent stricture which will require frequent dilations.

The author has utilized this anatomical situation both as a diagnostic aid and as a guide in treatment. He has found that on rectal palpation in those instances in which the urethra has been completely divided at the apex of the prostate he was able to locate the apex of the prostate and to push it up and away (Fig. 1). Conversely in those instances in which the prostate could not be dislodged with the examining finger the urethra had not been completely torn across.

The nature of the pelvic injury usually precludes placing a patient in the exaggerated lithotomy position necessary for doing a primary suture of the divided ends of the urethra. This has led the author to attempt to restore the continuity of the urethra by bringing traction on the prostate to return it to its correct anatomical position. Traction has been accomplished with the aid of a Hagner or Pilcher bag or, preferably a Foley balloon catheter. A urethral sound is passed through the urethra to the site of rupture and then guided into the prostatic urethra by introducing a finger into the posterior urethra through a suprapubic cystostomy incision and in that way guiding the sound into the bladder. The distal end of the catheter is threaded on the sound and withdrawn through the urethra, bringing the bag to rest upon the upper surface of the prostate gland. Traction is best maintained by tying the catheter to a band which has been fastened to the lateral aspect of the knee just below the patella. In this way, traction is maintained constantly regardless of whether the knee is straight or flexed. Tension is maintained for 3 weeks, after which the catheter is left in place for an additional 2 weeks.

In a sufficiently large series of cases, the author has successfully prevented the development of severe strictures.

CHARLES V. HOOVER, M.D.

Faldsønd A. B.: Abacterial Pyuria Presenting as Urethritis. *Brit. M. J.* 1946, 2: 493.

In view of the increasing recognition given to this clinical syndrome (Donovan, 1945; Peters, 1946) the records of 3 cases, noted over a period of 3 months at a military hospital in the United Kingdom, are presented in detail.

The patients had reported as sick, or were referred to a special treatment center on account of persistent urethral discharge. Two cases had been seen on previous occasions and were given courses of sulfathiazole, urethral irrigations and intravenous fever therapy (F.A.B. vaccine) but with no permanent relief from their symptoms.

These patients had all received the recognized treatment for cystitis and urethritis, but in no case had a permanent cure been effected. Specific urethritis was excluded. A cystitis was assumed in all cases, but no organism could be detected after repeated attempts at culture. In the 3 cases presenting a synovitis of the knee, old gonococcal infection was excluded.

Causation is discussed by Donovan (1945). Renal causes were excluded in his series of cases, and a virus cause was suggested whether organic arsenicals have any therapeutic value in a virus infection is questioned by the author (Peters, 1946). According to Lydon (1945) recurrent attacks simulating pyelitis occur during the course of trichomonas vaginalis infection in the male. In view of this the author ventures to suggest trichomonas vaginalis as a possible cause of abacterial pyuria.

As the 3 patients in question had received prolonged treatment by the recognized therapeutic

measures, with no permanent relief the effect of intravenous neosphenamine was dramatic in its action. Follow-up on these 3 patients was limited to one month because of constant troop movements, but no recurrences of the condition were reported. It would be interesting to know whether any other investigations have been carried out to explore the possibility of trichomonas vaginalis as a potential cause of abacterial pyuria.

JOHN E. KIRKPATRICK, M.D.

GENITAL ORGANS

Dalporto, T. V.: Genuine Prostatic Lithiasis (La litiasis prostática verdadera). *Bol. Soc. cir. Ecuador*, 1946, 13: 50.

The author concurs with others in his opinion that there is no pathognomonic symptom of prostatic lithiasis. The general picture is that of a chronic prostatitis or other prostatic affection, and therefore he recommends that all roentgenological examinations of the urinary passages include the region of the prostate.

As regards calculi in the region of the posterior urethra, however, a sharp distinction may be made between the stones which arise in other parts of the urinary tract to later become lodged in the posterior urethra, and calculi which develop and remain embedded in the prostate itself. The former are apt to cause sudden fulminant symptoms with complete obstruction of the urinary stream; the latter are apt to be more chronic manifestations with gradual and usually incomplete urinary obstruction.

In only 1 of the author's 8 patients was there any pain in the region of the loins and this pain was never comparable to a Dietl's crisis. In this case there was evidence roentgenologically of dilatation of the kidney pelvis which was ascribable to a moderate degree of nephroptosis. Urethral structure was usually present in fact, in only 3 instances of this material did the urethra appear to be entirely normal in caliber. The stones were always multiple and varied in size from that of a hazelnut to mere sand.

The urethroscopic route is preferred for treatment by the author perhaps after dilatation of the structure. By this route not only can the larger calculi be grasped and removed perhaps with the finger in the rectum aiding the manipulations, but many of the small stones can be washed out directly. In 3 instances, however, the perineal approach to the condition was chosen—both had cystoperineal, or cystorectal fistulas—and in 2 instance a suprapubic cystostomy was done. The author did not attempt a prostatectomy, and, in particular, did not attempt performance of the radical extracapsular prostatectomy of Henline.

The author regards the endoscopic method as ideal both for diagnosis and for removal of the concretions, even when the operation has to be repeated, so long as the stones are not larger than a pea. However, even with the larger concretions the stone may be rocked out of its bed, with perhaps the aid of the

finger in the rectum pushed back into the bladder and later broken with the lithotrite. Following removal of the calculi prophylaxis would seem to suggest subsequent attention to the usually accompanying strictural condition. Of course, chemotherapy is recommended for the secondary infectious processes.

In 3 of these patients crystallographic study of the calculi proved a predominance of calcium carbonate in their composition. JOHN W. BROWN, M.D.

Neelitz, R. M., and Plumb, R. T.: Prostatic Carcinoma. *Surgery* 1946 20 263.

The purpose of the present report has been to provide data on a large series of patients with cancer of the prostate who have been followed for periods up to 10 years.

Comparative data in the series studied indicate that survival rates are significantly prolonged by endocrine modifications. Whether other or comparable series would show a similar advantage in favor of endocrine therapy of patients with prostatic carcinoma can only be a subject for speculation but the comparative survival rates among patients with metastases suggest that castration or catrogenic therapy has a beneficial effect on the survival curve.

Only a study of the final data on closed series of cases will disclose how the longevity of the greatest survivors in each series will compare, and will settle the question regarding a possible acceleration of neoplastic activity in isolated cases by modifications of hormonal status. JOHN A. LOFF, M.D.

Cox, H. T.: Carcinoma of the Prostate. *Brit. M. J.* 1946, 2 191.

Thirty cases of late carcinoma of the prostate treated by transurethral resection of the prostate and stilbesterol therapy at the Withington Hospital, Manchester are presented. Normal micturition was restored in every case except one. The author prefers the cold punch to the diathermy loop because he believes that the latter may be followed by large sloughs. As much malignant tissue as possible should be removed, down to the prostatic capsule and from all four quadrants.

The most obvious effect of stilbesterol therapy is the dramatic and rapid relief of metastatic pain. The author believes that the dosages employed are often too low and that apparent failures of stilbesterol therapy may be due to this cause. Disastrous results may follow continued treatment on a lowered maintenance dose, even when the dose is reduced at a time when the malignant process appears to be under control both clinically and pathologically. In the later cases in this series treatment was started on 30 mgm. of stilbesterol daily.

Cardiac complications developed in 4 cases as a result of stilbesterol therapy. When dieneestrol was used instead, complete relief was obtained in each instance. This substance is said to be three times as active catrogenically as stilbesterol.

Pathological grading of the lesion according to Muir's classification is an important step in the treat-

ment of carcinoma of the prostate. It provides an approximate estimation of the survival period. A lack of this knowledge may render fallacious any attempt to interpret, in terms of survival periods the benefit of catrogen therapy or any other therapy.

The acid serum phosphatase estimations are classified into three groups: those below 4 units per 100 milliliters as normal, those between 4 and 10 units as suspicious and those at or over 10 units as diagnostic of carcinoma with secondaries. No case of a false positive has been recorded in this series; the word positive referring to a figure of 10 or over. Advanced Paget's disease constitutes the only exception. In this condition, however, there is an extremely high level of alkaline phosphatase as opposed to the very moderate elevation found in carcinoma of the prostate.

False negatives (carcinoma with secondaries and a low acid serum phosphatase) are known to occur but their incidence in 50 per cent of cases is sufficient to limit the value of the test and to discredit the value of all normal readings. These experiences show how fallacious the practice of relying on the acid serum phosphatase estimation for the control of stilbesterol dosage may be. FREDERICK A. LYON, M.D.

Arias, O.: Clinical Forms of Nicolas Favre's Disease (Las formas clínicas de la enfermedad de Nicolas y Favre). *Rev. urol. Mexico* 1946 4 364.

Arias discusses the clinical forms of Nicolas-Favre's disease. He considers the following forms of infection as developing through the genital organs: Lymphogranulomatous chancre, which appears in different forms and takes the herpetiform type in 73 per cent, simulates syphilis in 18 per cent, takes a nodular form in 9, simulates Dugrey's chancre in 6 and produces an infiltration in the layers in 3 per cent.

He considers also the lymphogranulomatous urethritis and the lymphogranulomatous meatitis. In the latter form he differentiates 4 types: the troncular lymphangitis, the early regional edema, the inguinolial lymph node invasion and the genitourinary invasion.

Four main forms of adenitis may occur in the disease: the latent form, adenitis simulating syphilitic adenitis, adenitis with sudden onset and general symptoms, and adenitis of slow evolution.

The author describes the sign of "lymph node shock" when despite acute inflammation of the lymph nodes, there is no tenderness in the inflamed region and the sign of "shakiness" produced by the displacement of the indurated lymph nodes over the deeper layers because of the lack of involvement of such tissues early in the disease.

In the late complications are included genital elephantiasis, urethropenial fistulas, urethroperineorectal syndromes, and rectal complications with or without stenosis. The last complications occur through the rectal lymphatics or through the urethroprostatic rectal lymph channels.

WILLIAM E. RICKETTS, M.D.

MISCELLANEOUS

Jeffcoate, T. N. A.: Male Infertility. *Brit. M. J.* 1: 185

In a large proportion of cases infertility results not from one but several factors which may be distributed between the two partners. A statement of the cause of childlessness in any marriage should consist in a listing of all the infertility factors present. Treatment should aim at the elimination of as many of the infertility factors as possible.

Physical examination of the male is of strictly limited value. If the findings are positive—e.g., atrophied testes—then they are significant but if the findings are negative no conclusion is possible. Male fertility is mainly assessed by semen analysis.

As a result of an assessment of male fertility in 491 private and 115 hospital cases of sterility the author has established the following criteria of sterility: (a) a semen volume repeatedly below 0.5 ml., or a total sperm count below 50 million (b) with this exception, no count above 30 million milliliter was considered abnormal (c) asthenospermia was diagnosed only if the motility was below 40 per cent at the end of from 6 to 8 hours (d) semen was not considered subfertile unless more than 50 per cent of the spermatozoa were malformed. The sperm count was considered the most important single criterion. A count of 10 million per milliliter or less, was taken to mean a serious impingement of fertility.

In the author's series pregnancies occurred with counts as low as 2 million per milliliter and also in several cases of azoospermia. He explains the latter by the probable presence of intermittent obstructions in the genital passages.

The treatment consisted of general health measures, the administration of Vitamin E (although its efficacy was questioned) and the use of gonadotropin. Although no claims were made as to the efficacy of the last named substance, a rather consistent increase in the sperm count seemed to follow in the 14 cases in which it was employed and prompt pregnancy followed after prolonged sterility in several cases.

Basal metabolic determinations were not made and thyroid extract was not employed by the author.

Among 169 men found to have seminal faults, 26 produced at least one pregnancy since their investigation and after treatment of either themselves or their wives, or both. **FREDERICK A. LYON, M.D.**

Werner, A. A.: The Male Climacteric. *J. Am. M. Ass.* 1946, 133: 88.

Werner reports 273 cases of patients with the "male climacteric." The symptoms of this syndrome may be present in eunuchism, cryptorchidism, hypogonadism, castration, and the climacteric. The most prevalent time for this decline of gonadal function (climacteric) is between the ages of 45 and 55 years.

Diagnostic evidence for the condition is chiefly subjective and results from gonadopituitary im-

balance, with disturbance of the autonomic and central nervous systems. The symptoms are (1) nervous, (2) circulatory and (3) general. There is an intense subjective nervousness or feeling of tension and tremulousness, especially during the night or in the morning, and irritability. The patients are hard to please, sleep poorly and are excitable. There is numbness, tingling of the hands, and formication. Vertigo and occipitocervical headache is common. There is decrease in memory in the ability for mental concentration, and depression or melancholia. Circulatory symptoms are hot flushes, perspiration, a smothering sensation, tachycardia, dyspnea, palpitation, cardiac consciousness, vertigo, and cold or tremulous. The patients tire easily, are debilitated, and experience a loss of potency with persistence of libido. Frequently constipation, distention and postprandial cruetation are seen.

Werner administers 25 mgm. of testosterone propionate every other day omitting Sunday for a month or two, and then twice a week for 1 month, and then once weekly. When the patient develops endocrine stability the symptoms do not return after cessation of the treatment.

Of the 273 patients studied, 230 were in the climacteric. The author warns that one can almost surely produce a climacteric patient relief from his symptoms and a feeling of well-being, but not a return of libido and potency.

DAVID ROSENBLUM, M.D.

Wilson, J. G., Leahy, A. D., and Benjamin, J. A.: Study of Experimental Urinary Calculi. *J. Urol. Balt.*, 1946, 56: 151.

The authors have previously described a method for the experimental production of urinary calculi in rats by multiple injections of estradiol dipropionate during the first two weeks of life. It was found that a high percentage of male rats so treated formed stones subsequently and the assumption was made that all such males were potential stone formers. A necessary condition for the formation of calculi was found to be that the animals must be fed on a well balanced diet which contained minerals somewhat in excess of the basal requirements for normal growth and reproduction. In animals, similarly treated, that were maintained on a diet that was nutritionally adequate but contained near-minimal quantities of minerals the incidence of stones was greatly reduced.

It was the object of the present experiment to determine whether the stone-forming potentiality was permanent or transient, i.e., dependent upon age, rate of growth, or some immediate sequelae of the hormonal treatment. The plan was to delay the early development of calculi by feeding treated rats for several months on a diet low in minerals, then to transfer the rats to a diet containing a surplus of minerals.

Treated males and females were fed the low mineral diet until they reached ages ranging from 235 to 257 days, after which a majority of both sexes

were transferred to the high mineral diet. Ten of 13 males developed stones within from 24 to 125 days following this transfer. None of the females of the similarly treated group developed stones. None of the control series of males and females that were maintained on a low mineral diet developed stones. Infection in the urinary tract did not seem to be a determining factor as with one exception all animals in this and in an earlier series showed evidence of infection at some time during the experiment. The reaction of the urine was thought to play a role as the urine of males on a high mineral diet became alkaline within a few days after the diet was instituted and remained so thereafter while the urine of control males (on low mineral diet) and of all females ranged from acid to neutral. A higher incidence of gross pathology of the urinary tract was found in males maintained on the high mineral diet. In females, the diet did not appear to affect the occurrence of abnormalities in the urinary tract.

The conclusion reached in the present study is that the stone-forming tendency induced in male rats by the methods described is not transitory and that it may be retained for several months in an undiminished though latent form. The interpretation advanced by the authors regarding the relation between diet and lithiasis is that the dietary content of minerals is the critical factor in stone formation in treated males. They postulate a series of changes in which initiated by the hormonal effects of hypertrophy (and possibly inflammation) of the lower genitourinary tract, there is narrowing of the urethral lumen and a consequent resistance to the flow of urine. This may predispose to urinary tract infection. A high mineral diet renders the urine alkaline. The cycle of stagnation, infection, and alkaluria continues to the point where normally soluble urinary stones become insoluble, crystallize, and thereby initiate the process of calculus formation.

CLARENCE V. HODGES, M.D.

Gieritz, G.: Enterococci in Urinary Tract Infections. *Acta chir scand.*, 1946 94 suppl 109.

Since its use by Thiercelin the term enterococcus has had a somewhat variable and hazy meaning. In some cases the name has been applied rather specifically as a synonym for streptococcus faecalis but most workers have used the term enterococcus in a loose group sense to designate faecal streptococci which have in common some of the outstanding characteristics of the streptococcus faecalis. Through the application of a wider assortment of tests and from more extensive studies of individual species, there has gradually evolved a rather definite and clearly defined enterococcus division of the streptococci.

The enterococci occur either in short chains or in pairs. The individual cocci are elongated and are sometimes almost bacillary. They are differentiated from other known species of the streptococci by their combination of low minimum and high maximum temperatures of growth, greater tolerance of salt and

alkali, high thermal death points, and resistance to relatively strong concentrations of methylene blue. The fermentation of mannitol is an especially constant characteristic. Inulin is only rarely attacked. Enterococci show a tolerance to bile, and some strains are able to liquefy gelatin which differentiates them from other streptococci.

The enterococci are divided into 3 types (Sherman): (1) the streptococcus faecalis, which is non-hemolytic and nonproteolytic (2) the streptococcus liquefaciens which is nonhemolytic and proteolytic and (3) the streptococcus symogenes which embraces all of the hemolyzing strains independently of their capacity to liquefy gelatin.

The author carried out a clinical bacteriological investigation of the urological cases which were being treated at the surgical clinic of Karolinska Sjukhuset (Stockholm) from May 1942 to July 1943. A total of 673 cases were studied, 383 of the patients being men and 290 women. Two hundred and seventy-three streptococcal strains were isolated from the urine, of which 240 (88%) were enterococci. One hundred and forty-two (50%) of the latter were nonhemolyzing and 45 of these (32%) liquefied gelatin. Ninety-eight (41%) were hemolyzing and 5 (5%) of these liquefied gelatin. The different types of enterococci seemed to show an equal ability to grow in an acid urine. Urines having a pH below 5 had a bacteriostatic effect. The enterococci do not show a tendency to split urea.

The effect of the following antiseptics was also studied: chloramine 1:100, rivanol 1:1,000, potassium permanganate boric acid solutions 1:4,000 and 1:400, silver nitrate 1:1,000, and chinosol 1:1,000. Chloramine produced its full effect in all tests after 10 minutes. The effect of the other solutions was irregular.

Discrepancies may occur between smears and cultures. A vigorous growth of the *Bacillus coli* can hinder or prevent the growth of cocci on solid media. The *Bacillus proteus*, if present, may by its extensive growth prevent the identification of other bacteria unless special cultures are employed. Further discrepancies may occur because of the nonviability of bacteria seen on the smear. Bacteria may be demonstrated for a longer time in smears than in cultures.

Contamination by urethral flora may present difficulties especially in voided urine specimens from men. This error is diminished but not entirely eliminated in second glass and catheterized specimens. In order to determine whether enterococci are normally present in the male urethra, the author tested 100 urine specimens. Enterococci were found in only 2 cases.

The *Bacillus coli* was the bacterium most commonly found in patients on admission. During the period of hospitalization enterococci were most usually observed. In more than every fourth case an enterococcal infection arose later. In general an enterococcal infection appears most clearly during, and in connection with treatment with the sulfona-

mides. Modern chemotherapy has shown the clinical importance of enterococci in infections of the urinary tract.

The enterococci are secondary invaders of the urinary tract. Of 216 of the author's patients infected with enterococci, only 38 displayed such infections on admission.

Enterococcal infection appears commonly in connection with catheter drainage. This was demonstrated in 151 of 189 cases studied by the author.

Infection with the *Bacillus coli* and staphylococci under corresponding conditions was only about half as common as infection arising from enterococci.

Enterococci are bacteria of relatively low virulence and invasive power. In the urinary tract they do not in some cases give rise either to subjective or objective symptoms, but in other cases they are able to cause slight distress and slight inflammatory changes. In cases in which more severe inflammatory changes existed the author was able to demonstrate the simultaneous presence of other bacteria.

It is questionable whether the enterococci play any significant role in the formation of calculi. The various types of enterococci are clinically equivalent to each other.

Sulfathiazole is ineffective in the treatment of infections caused by enterococci. If this drug is given prophylactically in catheter treatment, the urine will nearly always become infected with enterococci in pure culture. Neosphenamine is likewise ineffective. Favorable results are obtained with mannitolic acid.

An enterococcal infection arising in connection with urological instrumentation almost regularly disappears unless a complication such as residual urine stricture or calculus exists.

FREDERICK A. LLOYD, M.D.

Fish, G. W.: Oxidized Cellulose (Absorbable Hemostatic Gauze, Cellulose Acid): Its Use in Genito-urinary Surgery. *J. Urol.*, Balt., 1945, 54: 271.

The author has used oxidized cellulose gauze to assist in hemostasis in a variety of urological operations. In suprapubic prostatectomy he inserts one or more rolls of 2 by 18 inch 4 ply gauze packs into the enucleated gland cavity and exerts grade but firm pressure for 2 or 3 minutes. When hemostasis is established the bladder is closed about a suprapubic tube which is removed after the fourth day. The gauze normally is absorbed within 10 days and excreted by the kidneys, and when removal needs to be expedited this can be accomplished by irrigations with 5 per cent sodium bicarbonate solution since the gauze is soluble in weak alkali.

In order to use this gauze successfully the following criteria must be observed: (1) the gauze must come in active contact with the bleeding point, and (2) a sufficiently large quantity of gauze must be used to cover the bleeding surface completely and if pressure is needed it is not necessary to apply it for more than 2 or 3 minutes.

The author used the gauze in 108 instances to control bleeding in the enucleated prostatic bed following suprapubic prostatectomy and in a few instances in virtually all types of urological operations, so that the total series represents 136 cases. The results have been gratifying in every instance, and the gauze was found to be particularly useful in nephrectomy in which a thin absorbable pad placed between the renal halves controlled the bleeding with the use of only a few xochromatic mattress sutures. The postoperative nephrectomy bed which is the site of much cortical collateral circulation also permits the use of this hemostatic gauze to great advantage.

patients with lesions of the bone. Finally, there were 3 patients whose lesions went on to suppuration without more or less extensive bone involvement. In the first of these groups the author believes that resolution of the condition could have taken place without penicillin. In fact he is unable to rule out the possibility of diagnostic error in these patients. In the second group of patients recovered without abscess formation, which is an abnormally high percentage (38.3) for such cases and might be construed as an argument for the efficacy of penicillin nevertheless 2 of the patients had been ill for 24 and 45 days respectively before coming under treatment and already showed signs of resolution of their conditions without suppuration.

the Park
JOHN W. RAY

The particular characteristic of the neuropathic rhithropathy is the endochondral ossification under the joint cartilage which ordinarily becomes a secondary lamella, while the so-called preliminary limiting ossification some becomes extensively revived. The first preliminary calcification is a forward pushing of the penetration of vascular marrow and the third step joint reacts on into the now calcified cartilage endochondral ossification. The degree of this ossification is so great and so diverse that by dint of congruity of the joint surfaces may result

The author describes a case in which a neuropathic joint developed in a patient who had been bedfast for 15 years. He believes that the continued pressure of the body weight is quite adequate to be a source of trauma in an insensitive joint. He believes the changes observed in neuropathic arthropathy appear to be brought about by repeated subclinical traumas occurring in an insensitive joint and that there is no definite evidence of the existence of trophic nerves.

EMIL C. ROSENBERG, M.D.

Schajowicz, F., and Alarcón, F. O.: Sarcomatous Change in Paget's Osteitis Deformans (La transformación sarcomatosa de la osteitis deformante de Paget) *Rev orlop traumat.*, B. Air 1946, 15-33.

In 1943 Schajowicz collected a bibliography of 53 cases of malignant degeneration of Paget's osteitis deformans from the world literature and added a case of his own. As the frequency of Paget's disease is not known, it is impossible to say just what proportion of cases undergo malignant degeneration, but it is probably about 7 per cent.

A new case is described in this article. The patient, a man of 63, had had chronic rheumatism for about 8 years. Within the past 3 months the pain had become localized at the lower end of the femur around the knee and he was obliged to remain in bed with the knee in semiflexion and external rotation. A roentgenogram of this knee showed the typical picture of Paget's disease with the mosaic appearance due to alternate destruction and new formation of bone. Smears made from a puncture showed many round, oval, and polyhedral cells with a moderate number of giant cells, most of them with only a few nuclei. The tissue was very rich in cells and blood vessels and, although it showed some resemblance to malignant giant cell tumor, a diagnosis of osteogenic osteolytic sarcoma (according to the North American classification of malignant osteoblastoma with myeloplaxen according to the classification of Brachetto-Brian) was made. Roentgenograms of the knee and pelvis and photomicrographs of the cell structure of the Paget's disease and the sarcoma were given.

The patient was given roentgen treatment with 3,000 units over several fields which relieved the pain, but another roentgenogram made 30 days later showed that the tumor had continued to progress. The patient is now being given daily injections of folliculin. Repeated doses of acid phosphatase are indicated in this case, although this remedy may be contraindicated in cases in which the rapid destruction of bone tissue causes an increase of acid phosphatase.

An endocrine factor has been suspected in the causation of Paget's disease, and various glands including the thyroid, parathyroids, and suprarenals, have been held responsible. However the author believes that the endocrine influence is from the male sex glands, as all but 4 of the 53 cases previously reported, as well as this 1, occurred in males, and the

macroscopic and microscopic pictures of malignant Paget's disease are quite similar to those of bone metastases from carcinoma of the prostate.

AUDREY G. MORAN, M.D.

McLaughlin, H. L.: Lesions of the Musculotendinous Cuff of the Shoulder: Observations on the Pathology, Course, and Treatment of Calcific Deposits. *Ann. Surg.* 1946, 134-354.

The Fracture Service of the Presbyterian Hospital in New York has had the opportunity to study almost 3,000 lesions in which the symptoms centered around a calcific deposit to produce the condition commonly diagnosed and treated as calcified subdeltoid bursitis.

Gross, microscopic and bacteriological studies of the condition have been possible in about 200 patients, including all stages of the condition, who were subjected to operation.

The earliest microscopic evidences of the lesion consist of hyaline degeneration in the collagen of the tendon fibers. The involved fibers soon become fibrillated and form loosened bands of fibers within the substance of the tendon. Motion of the part, aided by progression of the local degenerative change, further loosens these fibrillated strands, finally breaks them free from their attachments to the more normal surrounding tendon, and casts them into rice-like bodies occupying a cavity within the substance of the tendon. Continued motion grinds these rice-like particles into a finely pulverized vesicle substance composed of necrotic tendon debris. Almost all deposits productive of pain in the shoulder contain a sufficient concentration of calcium salts so that their presence and anatomic location become demonstrable by adequate roentgenological studies of the part.

Quiescent calcific deposits are encountered roentgenologically. So long as the deposit remains buried in tendon it tends to remain quiescent, but sooner or later it gradually or suddenly penetrates the overlying tendon fibers to come into contact with the floor of the subdeltoid bursa. Operative findings have demonstrated that the degree of inflammation varies in accordance with the quantity of irritant material in contact with the bursal floor.

The deposit productive of chronic symptoms invariably is dry cheesy or waxy and infiltrated through tendon tissue within a relatively poorly circumscribed cavity under little or no tension. The deposit productive of acute pain is always wet, greasy of the consistency of tooth paste or heavy cream, and is under distinct tension within a rather well defined cavity from which the material is apt to well defined cavity from which the material is apt to logically manifested by a rather dense shadow with an ill-defined or irregular periphery whereas the acutely inflamed deposit is represented by a well defined globular and frequently flocculent shadow of relatively less opacity.

As for treatment the immediate problem usually demands a decision between curative and purely

palliative therapy. Seldom is anyone but the patient qualified to make such a decision.

The chronic condition warranting curative therapy deserves operative removal of the deposit as the only certain and speedy method of obtaining permanent relief. The chronic condition warranting nothing more than palliation may be treated by any combination of sedative measures that are convenient and that result in reduction of pain. Simple home measures including heat, aspirin, and a program designed to prevent disuse and stiffness of the arm have been found to be as efficient as all types of formal therapy.

The acute condition warrants curative therapy. The treatment of choice is puncture of the tense deposit and aspiration of its contents by needle under local anesthesia. Palliation usually is necessary during the next few days. Multiple deposits in the acutely inflamed shoulder and certain other selected acute cases warrant operative intervention.

RUDOLPH S. REICH, M.D.

Smith, F. M.: Displacement of the Medial Epicondyle of the Humerus into the Elbow Joint. *Ann. Surg.*, 1946, 124, 410.

This article reviews and evaluates the results in 21 consecutive cases of fracture of the epiphysis of the medial epicondyle of the humerus with displacement into the elbow joint. Each of these cases was either accompanied by a posterior or posterolateral dislocation of the elbow joint or had been subjected to reduction of such a dislocation previously. Each case was treated by open operation. Of the 21 cases thus treated, 20 have been followed carefully for years, the average follow up period being between 4 and 5 years.

Displacement occurs mainly between the ages of 7 and 17 years. There are two main types, namely (1) mild to moderate separation of the epicondyle from the condyle and (2) complete avulsion of the epicondyle with downward and lateral displacement and incarceration into the elbow joint. This article deals only with the second of these conditions.

Diagnosis by clinical examination is extremely difficult because of the large amount of early swelling and acute tenderness. The condition may be suspected if there is obvious dislocation of both forearm bones and the usual marked prominence of the medial epicondyle cannot be palpated in its normal position. However, the displaced epicondyle when not felt in its normal location may have swung posteriorly as a stripped-up periosteal attachment and not be truly in the joint cavity. Roentgenological examination is the only sure and safe way to make the diagnosis. If there is any doubt about where the epicondyle is, films of the uninjured elbow in identical positions should be made for comparison. An important part of the clinical examination should be to test both sensory and motor function.

At operation the medial aspect of the elbow joint may be exposed either through a longitudinal incision or a transverse one along the flexion crease. When the joint is exposed the nearly circular medial

aspect of the trochlear process is seen covered by articular cartilage. Immediately below this are seen the converging fibers of the glistening white fascia overlying the surface of the flexor-pronator muscles. These fibers and muscles curl laterally into the joint cavity just distal to the trochlea. If this fascia is pulled upon by a mouse toothed forceps, the incarcerated epicondyle will "pop out" into full view. It can then be reattached to its original site or it can be excised.

There were 7 patients who also presented ulnar nerve palsy on admission and 1 case showed a temporary palsy after operation. All of them recovered complete function of the nerve.

The patients who responded best and promptly and who have continued to do so are those that were immobilized in a posterior molded plaster splint for less than 3 weeks after operation or had only a sling.

Summing up the end results, 6 patients obtained completely perfect results, 4 have excellent results, 9 have good to excellent results, and 1 has a fair to good result. The remaining patient died of the anesthesia on the table before the wound could be closed. From the economic standpoint every patient followed up showed complete use of the elbow with out any handicap whatsoever.

RUDOLPH S. REICH, M.D.

Marottó O. R.: Synovial Sarcoma (Malignant Synovioma) of the Elbow (Sarcoma sinovial [sinovioma maligno] del codo). *Rev. As. Méd. Argent.*, 1946, 60, 505.

A 23 year old patient noticed a swelling of his left elbow 8 years prior to admission to the hospital. The mass caused only slight pain in the beginning but gradually the intensity increased.

Inspection revealed a globular deformity of the left elbow. The local temperature was increased. On palpation the tumor appeared to be of a solid character but had an elastic consistency and was not attached to the skin. There was no adenopathy. Flexion and extension of the left elbow were markedly limited while supination and pronation were not affected. Roentgenograms disclosed a shadow corresponding to the location of the tumor with evidence of calcification.

Two days after biopsy an amputation of the upper third of the left arm was performed under general anesthesia.

The dimensions of the tumor were 8 by 3 1/2 cm.

The histological examination revealed the presence of connective tissue and adenomatous cavities.

From the purely histological point of view tumors originating from the synovia may be classified as endotheliomas, peritheliomas, or sarcomatous endotheliomas but their origin from the synovia justifies the term synovioma or synovialoma. Histological and clinical evidence of malignancy explains the generic term synovial sarcoma.

The evolution of such tumors is usually slow averaging 5-7 years. Metastases are found most frequently in the lungs. According to Lewis calcareous

deposits visible in roentgenograms are pathognomonic.

Conservative surgical procedures such as extirpation of the tumor lead to disaster. Early amputation with extirpation of the lymph glands is the method of choice.

JOSSELYN K. NARAY, M.D.

Nolia, M. C.: Congenital Luxation of the Knee (Sobre la luxación congénita de la rótula). *Cirugía por locomotor* 1946 3 65.

Only 2 cases of congenital luxation of the knee were seen among 18 000 admissions to the orthopedic service of the author's hospital. Females are more often afflicted than males. Many hypotheses are advanced regarding the origin of the disability. It is seldom observed before the first decade and then it usually follows some trauma.

In minor cases mechanical appliances are employed—massage, physical therapy and similar measures. These are ineffective in advanced cases. The various operative techniques are named in accordance with the tissue attacked, such as bone, capsular ligament, tendons, or muscles.

A case report is presented of a patient who had high grade luxation of the knee which produced no symptoms. The condition was recognized following a fall. At operation none of the standard techniques, such as arthrodesis, arthroplasty, and petiectomy could be employed as the structures generally utilized were absent, rudimentary, or otherwise inadequate. Simple arthrodesis was followed by complete normal function.

STEPHEN A. ZIEGLER, M.D.

Rozas, J. T.: Plasmacytoma of Both Legs (Plasmocitoma cruris duplex). *Cirugía por locomotor* 1946, 3 8.

Rozas discusses a case of bilateral femoral plasmacytoma associated with simultaneous pathological fracture in a 50 year old man. The tumors were osteolytic without evidence of periosteal reaction.

Multiple myeloma, when typical, offers little difficulty in diagnosis. However, the many variants because of resemblance to other diseases, present diagnostic problems of the highest magnitude. These lesions arise from the red bone marrow cells, are osteolytic, and are definitely malignant. The bones chiefly affected are the vertebrae, ribs, cranium, pelvis, and, least frequently, the femur and tibia.

There are 4 recognized histological types, depending upon the character of the predominant cell, the plasmacytic, myelocytic, erythroblastic, and lymphocytic. Clinically the classification is of little significance and there is no characteristic syndrome. There is at times some rheumatoid or neuralgic pain frequently the first sign of the disease is a spontaneous fracture or a fracture following an insignificant trauma. There may be an anemia suggestive of the pernicious form. Other symptoms depend upon the location of the tumor. Stereal punctures are especially helpful in diagnosis.

Characteristic of the disease is the disturbed protein metabolism and the appearance of Bence Jones

albuminuria. Roentgenologically the process appears to be osteolytic, and the bony reaction is similar to that of diffuse osteoporosis.

The differential diagnosis must be made from metastatic carcinomatosis, osteitis fibrosa, Schaeffer-Christian and Paget's diseases, and osteoblastic sarcoma, or Ewing's tumor.

Considerable controversy exists over solitary myelomas. Their localization is in the thoracic vertebrae, pelvis, femur but most frequently in the cranium, cervical vertebra, and rarely in the mandible, clavicle, tibia, and sternum.

Two other case histories are given, 1 of a 63 year old woman whose chief complaints were those of attacks of lumbago. Roentgenograms showed a pathological fracture of the body of the first lumbar vertebra. The other case demonstrated an apparently solitary myeloma in a 51 year old woman who suffered a pathological fracture of the body of the seventh thoracic vertebra.

STEPHEN A. ZIEGLER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

D'Aubigné, R. M. and Lance, P.: The Treatment of Bone Defects of the Upper Extremities in War Casualties (Traitement des pertes de substance osseuse du membre supérieur chez les blessés de guerre). *Mém Acad. chir. Par.* 1946, 73 85.

The author had the opportunity to treat 60 cases with loss of bone substance which have occurred within the last year. Thirty-five patients have had bone defects of the upper extremity and the rest have had defects of the lower extremity. The results of the treatment of bone defects of the upper extremity are reported in this article and the end results of the treatment of defects of the lower extremity will be reported at a later date.

This article does not offer a new way of treatment based on biological, physiological and operative techniques, but describes one way of treating these cases. Twenty-six patients had loss of bony substance of the diaphysis, 5 of whom were operated on after 3 months. There were 18 cases of bone defect of the humerus which showed union of the fragments, 1 bone graft was fractured. There were 5 cases involving the forearm and 4, the ulna, 3 of which healed normally and in 1 case the bone graft was broken. Three cases had bone loss of the radius and all 3 healed completely. One case of bone loss of the metacarpal healed satisfactorily. Two cases of bone loss of the upper portion of the humerus were treated with fibular grafts with fair results. Three arthrodeses of the shoulder were done with iliac bone grafts and very good results were obtained. There were 2 cases of bone defect of the lower humerus which were treated by iliac bone grafts with good results. Two cases of bone loss of the lower extremity of the radius were treated with cubital and tibial bone grafts. Both healed very well.

The author's first concern was the treatment of the infection. In most all cases the extremities were in-

ected at the time they were first seen. It is not the purpose of this article to discuss the treatment of osteomyelitis, but the fact is worth mentioning that very rarely follows a prolonged course. Twenty-six of the 35 patients observed were completely healed at the time that they arrived at the center. Nine had ulceration or fistula and 2 of them had to be treated for osteomyelitis but could not be operated on because of this fact. The remaining 7 had to be treated on the following lines: 1 case by removing the sequestra in 2 cases by 3 grafts in 2 other cases by secondary suture and in 1 case by pedicled grafts, in 1 case spontaneous healing occurred. A delay of at least 1 month after the complete healing of the skin is indispensable before any bony intervention is contemplated. In spite of the short waiting period the author had only 1 case of late infection (5 months after the operation), no graft was lost and no suppuration occurred. This fact is probably due to the penicillin therapy which had been given systematically before and after the operation. One hundred thousand units of penicillin were given 3 days prior to the operation and were continued in cases in which an elevation of temperature persisted. The observation was made that the risk of an infection is less serious in the upper extremity than in the lower one where infections are more frequent and much more serious.

No bone operation should be undertaken unless the skin covering this area is adequate. In most of the cases the skin was adherent to the bone, of poor quality and ready to form ulcers. These scars should be resected and replaced by pedicled grafts. On the forearm and on the hand abdominal tubular grafts were used. This graft from the abdominal wall was removed in the usual manner. On the arm where the skin is looser it was usually possible to cover the lost skin by a rotation graft from the immediate neighborhood. The donor area of the skin graft was immediately covered by a free skin graft.

The proper treatment of loss of bone substance presents two important problems: (1) the replacement of the missing bone, and (2) the immobilization of the fragments. These two problems are intimately related because the fixation of the fragments should be complete and prolonged. It is impossible and dangerous to count on an external apparatus to give proper immobilization. The immobilization should be instituted right on the bone itself. The following technique was followed.

In certain cases the two fragments could be approximated. This method was indicated particularly if the loss of the bone substance was associated with a loss of a portion of a nerve. Two cases with radial nerve fusions were treated in this manner with excellent results. If the lesion was localized too close to the upper extremity the diaphyseal fragment was impacted into the epiphysis and fixed with wire. This method was employed in 1 case with a good result. If one applies this method to a lesion localized into the diaphysis of the humerus the fragments

must be carefully and solidly fixed. For this purpose a bone plate was used, but as a rule a tibial graft is preferable. A Kuentscher spike was used in 1 case. This method assured an excellent alignment but there was a tendency for the fragments to separate. This happened in 1 of the authors' cases. It became necessary to use a bone plate in addition to the intramedullary fixation. There were 5 unions in 6 cases of loss of bone substance in the diaphysis of the humerus and 1 delayed union in which it was necessary to employ a tibial graft following the use of a Kuentscher spike. In cases of bone defect of the arm and in most cases of loss of bone substance of the forearm the normal length of the bone should be preserved and the loss of bone substance should be replaced by bone grafting. Iliac and tibial grafts were used. The tibial graft is very rigid and assures a firm immobilization it should be the method of choice in cases of loss of bone substance in the forearm.

In the beginning an inlay bone graft was used. In the proximal fragment the tibial graft was used as an inlay graft and was introduced into the medullary canal of the distal fragment. This resulted in a fracture of the graft. This type of treatment was completely abandoned. Finally the following technique was followed.

The two ends of the fragments were prepared only on one of their sides in order to preserve their blood supply. The length of the bone graft was accurately measured. The graft was taken from the medial aspect of the tibia. The length of the graft should be at least three times as long as the bone defect. With removal of the graft from its bed four holes are drilled into the graft. After removal of the graft cancellous bone was also removed. The graft was fixed into the recipient area by screws that were exactly measured. The periosteum on the donor site was united with catgut.

The tibial graft offers the advantage of being very solid. However at the same time it has the disadvantage that due to its density its revascularization is very slow. The iliac graft offers considerable advantage from this point of view. The technique for the use of iliac grafts is comparatively simple.

A curved incision is made over the iliac crest. The muscular insertions are detached subperiosteally and the graft is removed from the underlying portion of the crest with the use of the electric saw. The iliac bone is readily permeated from all sides by buds of connective tissue. However it is less solid than the tibial graft and it cannot be utilized in as long a piece as the tibial graft. Therefore it is necessary very often to use it together with a bone plate, a Kuentscher spike.

Destruction of the upper extremity of the humerus presents a difficult problem. If the bone destruction is limited and the muscles are preserved, one could suspend the humerus by a wire through the coracoid or acromion process as proposed by Leryche and Patel. The author has used this method in 1 case. In another case the loss of the bone substance was

considerable but the deltoid muscle was intact and the missing humeral head was replaced by the upper extremity of the fibula. The 2 patients in these cases have preserved good motion of the shoulder but abduction is considerably limited. In cases in which the destruction of bone is associated with destruction of the surrounding muscles, fusion of the shoulder is necessary. In 3 cases iliac grafts were employed with excellent result. The humerus was maintained in position with the Kuentcher spike which was inserted into the scapula. In cases in which the distal extremity of the radius is lost it is advisable to use a tibial graft which is attached to the diaphysis of the radius and impacted into the first row of the carpal bones.

In conclusion the author offered the following suggestions: (1) do not operate unless the skin is loose and well vascularized, (2) use grafts favorable for bony union (the cancellous bone of the iliac crest is one of the best sources), (3) always respect the vascular supply of the bony fragments, and (4) assure a firm fixation of the fragments and of the bone graft and do not rely on the immobilization of a cast.

GEORGE L. KRAM, M.D.

Etienne, E., Lapeyrie, M., and Campo A.: The Route of Internal Access to the Hip Joint (La voie d'accès interne de l'articulation de la hanche). *J. chir. Par.* 1944, 64: 115.

With regard to the route of internal access to the hip joint, the authors state that if the thigh is in a position of flexion, abduction, and external rotation, the distance from the medial aspect to the head of the femur is reduced to almost half as compared with the normal position; the average distance from the skin to the head of the femur being only 4 to 5

cm. Furthermore, the joint is easily accessible through the gap of the adductor muscles, and better exposure of the round ligament can be obtained than in any other position.

The technique of operation is as follows: a longitudinal skin incision of 7 to 10 cm. is made on the medial aspect of the thigh, two fingers breadth distally from a line drawn between the pubic spine to the ischial spine. The joint is approached between the internal rectus and the great adductor then between this muscle and the small adductor. The posterior branch of the obturator nerve is exposed. The capsule of the joint is incised in the longitudinal axis. In order to expose the round ligament, the thigh is rotated internally.

The advantages of this method are that the operation is not mutilating; all muscles, important vessels, and nerves are spared; a short incision is sufficient; the shock of operation is reduced to a minimum; the joint is approached from the inferior and medial aspect, in which region the capsule is less important functionally and the round ligament is easily accessible.

This method of procedure is indicated for open reduction of a congenital luxation, drainage of the joint, and resection. The authors believe that approach to the joint from the medial aspect of the head of the femur is preferable to other methods in all cases except those in which extreme abduction cannot be accomplished because of an old ankylosis.

WERNER M. SOLWING, M.D.

FRACTURES AND DISLOCATIONS

Caffey J.: Multiple Fractures in the Long Bones of Infants Suffering from Chronic Subdural Hematoma. *Am. J. Roent.* 1944, 56: 165.

The author presents a report of 6 cases of chronic subdural hematoma and associated multiple fractures of the long bones in infants. None of the infants were believed to have suffered any injury to the long bones, and there were no roentgen or clinical evidences of general or local disease which would account for a predisposition of the bones to pathological fracture. The majority of fractures of this type develop after the onset of the subdural hematoma. In the cases described the fractures appeared to be of traumatic origin but the traumatic episode and causal mechanism remain obscure. Roentgen examination of the long bones in patients with subdural hematoma is necessary for the identification of fractures, since many of them are silent clinically and the presence of unexplained fractures in the long bones warrants investigation for subdural hematoma.

EMIL C. ROSENTHAL, M.D.

Salaverrri, M.: Articular and Nerve Complications following Epitrochlear Fracture (Complicaciones articulares y nerviosas de las fracturas de la epitroclea). *Chir. y ginec. 1946* 3: 56.

Although epitrochlear fractures in themselves are relatively simple, the complications which may oc-

cur are extremely grave as far as the rehabilitation of the arm is concerned. This is due to the structural relationship of the epitrochlea to the ulnar nerve, the articular capsule, and the humeroulnar articulation.

A displaced epitrochlear fracture fragment with rupture of the internal ligament may result in fibrosis of the capsule, limitation of extension, disproportion of the internal humeroulnar articulation, separation of the superficial articulation and formation of a valgus. In addition to these mechanical disturbances, the ulnar nerve may become involved because of the distention, traction, inflexion and pull on the fragment or secondarily by its incorporation in the fibrous cicatrization of bony callus.

In the treatment one must consider the dislocation, the possible valgus deformity, interference of superficial radiocondylar articulation and the formation of a permanent lateral displacement. If surgical intervention is contemplated one of two procedures is offered: (1) the surgical extirpation of the fragment, or (2) its fixation to the humerus with catgut.

Salaverry describes his personal experiences in the management of these fractures; he employed traction after effective manual reduction and followed each case closely with the aid of roentgenography and by being alert to the patient's unannounced symptomatology. When nerve injuries existed liberation of the nerve was accomplished surgically by resection of the fibrous cicatrization or bony callus, or by transplantation of the nerve if indicated.

Eleven case histories with 20 roentgenographs are presented and the treatment in each case is indicated.

STEPHEN A. ZIMMAY, M.D.

Bannerman M. M.: Fractures of the Carpal Scaphoid Bone; An Analysis of 66 Cases. *Arch. Surg.*, 1946 55 164.

A series of 66 cases of fracture of the carpal scaphoid is reported covering a period of 3 years at two large Army General Hospitals. This series constitutes 3 per cent of all the fractures seen during this time. Forty two per cent of the fractures of the scaphoid bone were not diagnosed at the time of injury. In 35 per cent of this series the fractures were diagnosed as sprains and were not examined roentgenologically or the roentgenograms were reported negative for fracture and the diagnosis missed. In instances in which pain and swelling of the wrist persisted and especially those with the pain and tenderness in the region of the anatomic snuff box, careful re-evaluation and re-examination of the wrist are indicated. Multiple roentgenograms of the wrist at the time of injury may be helpful in making diagnosis.

In 85 per cent, or 56 of a series of 66 cases the fracture of the carpal scaphoid seen within 12 months after injury healed by prolonged immobilization in a skin tight cast including the thumb. All fractures less than 6 months old healed by this method.

Operative intervention was not instituted until after at least 2 months of immobilization without improvement. Operative treatment was performed in 10 cases. Six fractures healed with good results. In 2 cases of fracture showing pronounced arthritic changes, the distal fragment was removed with good results in 1 case. The type of surgery used in these cases is not described.

C. FRED GORING, M.D.

Daumerle, L. and De Koerle, E.: Fractures of the Neck of the Femur (*Les fractures du col du fémur*). *Brussels med.* 1946 36 649.

On the basis of the work done by Pauwels, the authors develop a theory of the mechanical forces involved in the healing of fractures of the neck of the femur and deduce the principles and technique of treatment.

In contradistinction to all other fractures of the body, only endosteal callus is formed in fractures of the femoral neck, but no periosteal callus formation occurs.

The formation of the endosteal callus is a slow process, particularly sensitive to the mechanical forces acting upon it. Bone formation is stimulated by pressure, whereas traction causes degeneration into connective or cartilaginous tissue formation, resulting in pseudarthrosis or nearthrosis. As no periosteal callus is formed, and as the neck forms an angle with the axis of the diaphysis, the beneficial action of pressure cannot take place when the patient gets out of bed and weight bearing is started. On the contrary the proximal fragment acts like the arm of a lever pulling the fragments apart and preventing consolidation. The more obtuse this angle of inclination, the more serious is the prognosis. The authors distinguish 3 categories of fracture, according to the greater or lesser obtuseness of this angle.

To avoid the danger of pseudarthrosis and the additional danger of hypostatic pneumonia and circulatory disturbances in elderly patients, the treatment of choice is internal fixation. The authors discuss the different techniques of this procedure in detail and advocate pegging with the Smith Petersen nail. To accomplish correct direction of the nail, the apparatus of Merle d'Aubigny is used. Since an incision of 3 cm. only is necessary, the shock of operation is negligible even in old patients. This method assures perfect consolidation whatever the angle of inclination may be and avoids the danger of circulatory disturbances.

In 26 of a series of 28 cases the authors had complete success with this method.

WERNER M. SOEMMER, M.D.

Incian, A. C.: Late Complications of the Fractures of the Neck of the Femur Treated Surgically (*Complicaciones tardías de las fracturas del cuello del fémur tratadas quirúrgicamente*). *Cir. ortop. traumatol. Habana*, 1945, 12 143.

Incian discussed the late complications of the surgically treated fractures of the neck of the femur.

The causes for such complications are listed as follows: bad reduction of the fracture, deficient maintenance after reduction, improper fixation of the fragments of the bones, improper placing of the osteosynthesis, infection and circulatory damage that lead to the absorption of the head of the femur, retardation of the consolidation, pseudarthrosis, and necrotic changes in the neck of the femur.

The appropriate selection of the better type of treatment is considered indispensable to avoid such complications and this selection must be individual in each case.

The bone graft with internal fixation by the Smith Petersen technique gave the best results in the fractures of the head of the femur and of the transcervical fracture of the femur with reabsorption of the neck.

WILLIAM E. RICKETS, M.D.

Olausson, T.: Intra Articular Fractures in the Upper End of the Tibia and Lower End of the Femur. *Acta chir. scand.* 1946 94: 407.

Fifty-one intra-articular fractures of the upper end of the tibia and 8 of the lower end of the femur are reported by the author. Nineteen of the fractures were located in the lateral tibial condyle; in 7 cases the medial condyle of the tibia was split; in 13 the fracture was bicondylar; in 6 small marginal fractures of the tibial condyles were found; and in another 6 there was an isolated fracture of the intercondylar eminence.

Of the 19 fractures in the lateral tibial condyle 14 were comminuted depressed fractures, 4 were non comminuted depressed fractures and 3 were splitting fractures.

Operative treatment was employed only in the last mentioned group. In most of the cases the fractures were treated by manipulations resulting in im-

perfect reduction. The entire material was treated during the period from 1931 to 1941.

A check-up of 51 patients in 1942 showed the results to be satisfactory in 38 and poor in 13. The poor results were attributable chiefly to the instability of the knee with abnormal lateral mobility, while deforming arthrosis played only a minor role.

The author concludes from his investigation that more frequent employment of operative procedure may be followed by better results.

JOSEPH K. NARIT, M.D.

ORTHOPEDICS IN GENERAL

Hudack, S. S.: A Study in Articular Replacement. *A. n. Surg.* 1946 124: 377.

An experiment was carried out in which chrome steel alloy was used to replace the humeral head in the dog. The donor element was seated into the medullary canal in the dog's shoulder. A series of 6 dogs was used. In general, full use was attained at the end of 3 months. On passive examination there was limitation of motion. Three of the animals survived the operation well over 6 months. A 5 year survival is reported. The postoperative course is explained in detail. The postmortem examination is reported in detail with a series of roentgenograms and photomicrographs. Three types of adaptive tissues surrounding the donor element are described. The tissue surrounding the nonweight-bearing part of the flanged nail is described as dense stratified connective tissue lying on flattened bone trabeculae. In the areas where there is weight bearing with compression stress, the tissue is more fibrocartilaginous. The areas where there is more stress show a combination of the fibrous and fibrocartilaginous elements.

RICHARD J. BICKETT, JR., M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Homans, J.: The Late Results of Femoral Thrombophlebitis and Their Treatment. *N. England J. M.*, 1946, 255-249.

The author presents the end results of thrombosis in the veins of the lower extremities and indicates that an obstructive inflammatory thrombosis is the late stage toward which all thrombotic processes tend. It is probable that this is by far the most frequent result of all the venous thromboses in the lower limbs. However many cases do undergo spontaneous cure. In some instances thrombi retain their soft character and when this occurs it is likely to cause pulmonary embolism.

In analyzing the 156 cases which formed the basis of the author's report, the late results of femorofemoral thrombophlebitis are presented in 5 groups, viz.

Group 1. In this group some degree of edema remains, so that the ankle and lower leg swell during the hours of work or standing, discomfort is an important congestion is not a feature the skin is healthy and the edema recedes or disappears over night.

Group 2. Here postphlebitic pigmentation and induration are present and ulceration in a variety of forms often occurs.

Sixty-one per cent of the author's cases fell into groups 1 and 2. The physical changes are considered by some to be due to sensitization of the tissues to foreign proteins absorbed from the feet, toes and nailbeds, the retained antigen causing vascular wall damage, and leading to extravasation of blood pigmentation and ultimately slow fat necrosis and scarring. Varicosity of the saphenous system, secondary to the original thrombophlebitis, contributes to the local disorder.

Group 3. In this group a pain complex becomes established early in the convalescence. Irrespective of all other signs this is often associated with vasomotor changes in the skin of the affected leg and a stockinglike paresthesia. Seventeen per cent of the cases were in this group.

Group 4. The leg is the seat of marked congestion.

Group 5. In this group recurrent thromboses occur in the deep and often in the superficial veins. The attacks, because they usually involve veins previously thrombosed and re-canalized are less severe than the original thrombophlebitis.

The recommended treatment is as follows:

Groups 1 and 2. Rest in bed with the legs slightly elevated the use of elastic stockings or a semi-elastic bandage from toes to knees when the patient is up and about treatment of the skin to do away with sources of absorbable protein substances derived chiefly from fungi saphenous vein section when this system is varicose radical excision and skin grafting should be used only occasionally.

Group 3. Almost invariably the condition is relieved by sympathetic lumbar block followed by relieving blocks or even sympathectomy in some cases.

Group 4. Since no valveless veins draining the lower limbs (except the iliac veins and the vena cava) are capable of forwarding blood against gravity and since the column of blood they contain transmits high back pressures on lifting straining and coughing their interruption must always benefit and can never harm the venous return. The recanalized thrombosed femoral vein may also be a source of the congestion seen in this group. The author recommends a study of the femoral and saphenous systems and if necessary an exploration by incision in the groin. If diseased the saphenous vein should be divided, as well as the common femoral vein if the vein below the entrance of the deep femoral vein is diseased.

Group 5. The best treatment for these cases of recurrent femoral thrombosis is ligation of the corresponding iliac vein. This high division secures the best collateral venous circulation and gives the greatest help in the prevention of future thrombosis and embolism.

EDWARD H. CAMP, M.D.

Fontaine, R., and Forster E.: Two Additional Cases of Gangrene of the Limbs of Venous Origin (Deux nouvelles observations de gangrène des membres d'origine veineuse). *Lyon chir.*, 1946, 41-173.

The two exemplars of this peculiar form of anoxemia leading to gangrene do not add anything to our knowledge of the subject nevertheless, the authors' cases are worthy of report because of the rareness of the condition and because of the emphasis to be inferred with regard to the necessity of a timely diagnosis.

The first case was that of a 40 year old male (apparently in normal health except for a somewhat shortened bleeding and coagulation time) who was subjected to an extensive hemorrhoidectomy. At the time of operation the hemorrhoids were discovered to be extensively thrombosed. The clots were removed by curettage. A couple of days later the right calf and the entire left leg became swollen and indurated. Later the process on the right side spread to the entire leg thigh and lower abdomen on that side and a few days after this the right foot developed evidences of gangrene. Eventually the left foot also developed patches of gangrene the process however remained limited to the toes more or less, with a small patch on the dorsum of the foot. All the toes on this foot were eventually lost except the fourth toe and the basal phalanx of the third toe. On the right foot, all of the skin, including that of the lower third of the leg, sloughed away, leaving the bare granulating derma. The toes on this foot, however, largely recovered without sloughing as did

the heel and the region of the achilles tendon behind. Skin grafts were applied to the bare areas and the patient was later able to walk without pain or other inconvenience. He resumed his former avocation (cabinet maker) and worked in the garden while at home. Excellent photographs depict the progress of the case and the final results obtained.

Arteriography was unsuccessful in this patient and amputation was decided against on the evidence of the enormous extent of the original edema, which suggested a venous rather than an arterial block, and persistence of the arterial pulsations in both extremities throughout the entire time.

The second case was that of an 8 year old boy who suffered a heavy fall on the left arm. The diagnosis, without roentgenological examination, was fracture of the left elbow. A splint was applied but was later removed because of the development of edema. The entire forearm became cold and blue and eventually gangrenous. At amputation the humeral artery was exposed initially and arteriography was attempted. This again was unsuccessful however the entire packet of vessels were extirpated en bloc from the amputated specimen. The artery of the arm was firmly contracted but intact, as were its branches. All of the veins on the contrary were blocked by recent thrombotic processes. The authors believe that a concomitant arterial spasm may favor the development of the gangrene but is not indispensable to its development.

JOHN W. BROWN, M.D.

Gross, R. E. Surgical Treatment for Dysphagia Lusoria. *Ann. Surg.* 1946 24 551.

Dysphagia lusoria has long been recognized as impairment of swallowing which occurs when a right subclavian artery arises abnormally from the left side of the aortic arch and then passes behind or in

front of the esophagus, and thereby compresses the esophageal tube. The condition was recognized as early as 1794 by Bayford. An anomalous subclavian artery can exist without making itself manifest. In occasional patients the disturbance in swallowing may be severe enough to interfere seriously with health and nutrition. Dysphagia is most likely to appear or to be aggravated (1) when the artery is taut and stretches across the esophagus like a bowstring (2) when the vessel becomes sclerotic and less elastic in the later years of life or (3) when there is aneurysmal dilatation of the artery. Copeland has discussed the detection of the anomaly by roentgenological studies.

The author reports the case of a four months old baby who was referred to the hospital because of difficulty in feeding. The symptoms had been progressive to the point where it was becoming difficult to feed the child because of regurgitation of undigested milk. Changes in the formula were without apparent benefit. Small amounts of cereal would be taken, but the child would refuse milk for several hours thereafter.

The child had gained in weight in spite of the feeding problem, but it was apparent that the increase was due to frequent small feedings rather than a normal schedule of feeding. The diagnosis was made by roentgenological examination after the ingestion of a thin barium mixture. The lateral projection revealed an indentation of the posterior wall of the esophagus at the level of the third thoracic vertebra. When viewed anteroposteriorly this filling lay in the oblique direction and suggested that there was an elongated narrow structure which ran upward and to the right between the vertebral column and the esophagus.

An operation was performed under cyclopropane anesthesia. An anterolateral approach was made through the left side of the chest, and the pleural cavity was entered through the third interspace. The third and second costal cartilages were divided, giving excellent exposure of the mediastinum. The aortic arch lay in normal position. The thymus was partially dissected and exposure was gained toward the patient's right so that the entire arch and its various branches could be adequately viewed. The right subclavian artery arose in an anomalous fashion from the posterior aspect of the left side of the aortic arch and then coursed upward and to the right, behind the esophagus. The right subclavian artery was liberated through its bed and then doubly ligated and divided near the aortic arch. The distal portion of the artery was permitted to retract to the patient's right and beyond the esophagus. Following operation, the child was given limited fluids for the first 36 hours, after which it was given a normal diet, with complete freedom from symptoms.

In summary the author points out that dysphagia lusoria can be treated by surgical means. He also stresses the fact that the intrathoracic heart of the subclavian artery can be divided with impunity because the second and third portions of the vessel

have collateral channels which are sufficient to maintain a satisfactory flow of blood to the right arm.

PAUL MERRELL, M.D.

BLOOD; TRANSFUSION

Aggeler, P. M., Howard J., and Lucia, S. P.: Platelet Counts and Platelet Function. *Blood J. Hemat.*, 1946 1: 472.

The purpose of this study was to determine the significance of reductions in the platelet count in terms of well established normal standards and to define the relationships which exist between the platelet count and the results of tests of the bleeding time, coagulation time, clot retraction and capillary fragility.

Observations of the bleeding time, coagulation time, capillary fragility, clot retraction and platelet count were made on each of 64 normal subjects and on 404 patients suffering from various diseases. Although the authors emphasize the point that the normal values for platelet counts must be ascertained in each laboratory by the person doing these counts, they found the normal value by the Roes and Ecker method to be mean 409,000 per cu. mm. with a normal range of from 173,000 to 545,000 per cu. mm. A significant relationship between the platelet count and the results of tests of bleeding time, clot retraction and capillary fragility was found but none could be established between the platelet count and the coagulation time. The authors discuss factors other than platelet count or platelet function which may influence the results.

The critical level of the platelet count below which abnormal bleeding is likely to occur was found to be 190,000 per cu. mm. in primary thrombocytopenic purpura, and 230,000 per cu. mm. in secondary thrombocytopenic purpura but this critical level is not an infallible one as exceptions in either direction were found.

In all cases of primary thrombocytopenic purpura and in most of those of secondary thrombocytopenic purpura, the bleeding time was markedly prolonged and the clot retraction definitely diminished. Similarly the tests were abnormal in about half of the patients with thrombocytopenic purpura without bleeding or with thrombocytopenic purpura associated with other hemorrhagic states. The capillary fragility was increased in about three-fourths of the patients with thrombocytopenic purpura, in one-half of those with secondary thrombocytopenic purpura and in less than one half of those with thrombocytopenic purpura without bleeding or thrombocytopenic purpura complicating other hemorrhagic states.

In the stage of recovery from thrombocytopenic purpura, dissociation of the tests was sometimes found and was of aid in predicting a remission of the disease. When the results of the tests returned to normal while the platelet count still remained below the normal range it was interpreted as evidence of the variability in the functional capacity of the platelets.

EDWARD H. CAMP, M.D.

Flink, E. B.: Blood Transfusion Studies. The Differentiation of Hemolytic and Nonhemolytic Transfusion Reactions. *J. Lab. Clin. M.* 1946 31: 1067.

It is emphasized that the plasma must be examined for hemoglobinemia after every transfusion reaction. Despite this accepted knowledge, the author states that in many reports transfusion reactions are being classified on the basis of the degree of fever and the severity of the clinical manifestations.

The reported incidence of all kinds of reactions varies between 3 and 5 per cent. Of these, the ratio of hemolytic reactions is quite low. In a series of 43,284 transfusions collected from the literature by Kilduffe and DeBakey the incidence of hemolytic reactions was 1.8 per cent for 1,000 transfusions, and the mortality 1.4 per cent.

Most investigators are agreed that unless the blood is more than 9 days old the age of the blood does not influence the incidence of febrile reactions. However, stored blood older than this tends to produce reactions.

Hemolytic reactions are most frequently caused by group incompatibility or are attributed to the occurrence of isogglutinins such as anti Rh agglutinins and occasionally to overheated blood. There have been many reports of the safe use of blood from universal donors.

Transfusion reactions generally fall into the following groups: (1) simple febrile reactions due to pyrogenic substances, (2) allergic reactions, and (3) circulatory reactions accompanied by intravascular hemolysis. It is pointed out that in most cases the hemolytic type of reaction cannot be detected by clinical signs alone.

The author has carried out a study to ascertain the significance of hemoglobinemia in reactions to transfusion. First a study of 38 transfusions given to patients with diseases associated with anemia was made by a careful technique to determine the plasma hemoglobin level. No significant hemolysis was noted. Nineteen febrile reactions to transfusions were studied and were proved to be nonhemolytic. Five cases of hemolytic reaction to transfusion were studied during the years 1942 and 1944 and the author believes that the finding of hemolytic reactions and early transient hemoglobinemia without hemoglobinuria in 3 patients substantiates the contention that hemoglobinemia is a fundamental and pathognomonic feature of intravascular hemolysis. One patient developed anuria and died as a result of uremia. This patient had had the highest plasma hemoglobin level observed in any of the 5 patients with hemolytic reactions which observation lends support to the thesis that the plasma hemoglobin level is an important factor in the development of renal damage.

In closing it is stressed that in the presence of any reaction the type whether hemolytic or non hemolytic, should be determined and a search made for the exact cause so that it may be eliminated.

LEROY J. KLEINSAMER, M.D.

RETICULOENDOTHELIAL SYSTEM

Imler, A. E.: Reticuloendotheliosis: With Report of 2 Cases. *Am. J. Roentg.* 1946 56 343

Single or multiple granulomatous lesions of bone with or without soft tissue involvement diabetes insipidus or exophthalmos, have been variously classified as certain forms of xanthomatosis, Hand-Schüller-Christian's disease, Letterer-Siwe's disease, lipoid histiocytosis, lipoidosis, lipoid granulomatosis, eosinophilic granuloma, solitary granuloma, and reticuloendotheliosis.

Following a review of the literature and the presentation of 2 cases from the Letterman General Hospital, San Francisco, California, the author finds that the separation of Hand-Schüller-Christian's disease, eosinophilic granuloma or solitary granuloma of bone and Letterer-Siwe's disease into specific disease entities is not valid on the basis of the evidence at hand.

There are insufficient data to support the claim of a lipid metabolic disorder as the primary causative factor. There are no pathological or roentgenological findings that warrant classifying these syndromes as individual diseases. It is believed that all these processes are variants of a hyperplastic reaction of the reticuloendothelial system and can be properly grouped under the term reticuloendotheliosis. Eosinophilic granuloma or solitary granuloma of bone represents a localized or focal hyperplasia of the reticuloendothelial system.

The stage of the disease process in the hypophysis and tuber cinereum will determine the response of the diabetes insipidus to roentgen therapy. Little or no improvement will occur if the infiltration is in the stage of fibrosis.

The pulmonary pathology is comparable to that found in the bones which in its early stages, is a granulomatous process and in the healing phase is almost entirely fibrosis. Pulmonary involvement in the early phase responds to deep roentgen therapy but lesions that have gone on to fibrosis show very little change.

Satisfactory response of the bone pituitary and pulmonary lesions can be obtained with relatively

small doses of roentgen irradiation. In the 2 cases reported, 600 roentgens, measured in air to any one field was exceeded on only one occasion. None of the skull lesions received more than 400 roentgens, measured in air through any one field.

BENJAMIN GOLDMAN, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Gonçalves, A. P.: Association of Brazilian Blastomycosis and Tuberculosis in Glandular Lesions (Associação de blastomicose brasileira e tuberculose em lesões ganglionares). *Rev. Brasil. med.* 1946, 3 535.

The author reports 2 cases of suppurative lymphadenitis, in which Brazilian blastomycosis was associated with tuberculosis.

In the first patient a mucous blastomycosis lesion of the right tonsil was associated with a suppurative axillary and cervical adenopathy with fistula formation, which was thought to be of the same origin. The second patient presented (in addition to Brazilian blastomycosis of the mucosa of the oral cavity and the cervical lymph nodes) an extensive pulmonary tuberculosis.

The correct diagnosis was established by means of inoculations in guinea pigs with pus obtained from the cervical nodes.

In the first patient the tonsillar lesion healed under the influence of sulfamerazine for a while considerable improvement of the lymphadenopathy was observed but later on it became stationary. The second patient succumbed to his condition.

Reference to the literature shows that the simultaneous occurrence of Brazilian blastomycosis and tuberculosis has been reported as such in only one patient.

Failure of the sulfonamides to produce a cure of Brazilian blastomycosis justifies a suspicion of concomitant tuberculosis, and suggests inoculation of guinea pigs.

The author gained the impression that tuberculosis inhibits to some extent the spread of *Paracoccidioides brasiliensis* infection.

JOSEPH K. NARAY, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Webster, G. V. and Rowland, W. D.: *Skin Grafting the Burned Dorsum of the Hand.* *Ann Surg* 1946 124 449.

When the dorsum of the hand is burned the elastic fibers which are situated very near the thin skin are easily damaged. This results in local fibrosis with stiffening and a seriously crippled hand.

The authors state that the type of surgery used in the care of this problem is dependent upon the type of burn. They divide the usual 3 "degrees" of burns into 8 groups, the first degree having 2 groups, and each of the other 2 degrees having 3 groups. As to the early care of the burned hand they believe that early grafting of this open wound is the ideal procedure when there is a full thickness loss. It prevents added loss of body fluids, it minimizes the amount of infection, it renders sterile an open wound at the earliest possible time and it prevents to a large degree the resulting crippling fibrosis which occurs when the wound is not covered. The treatment, therefore, is directed toward closing the wound at the earliest possible moment. This includes cleanliness, compression and rest, although it is believed that splinting is contraindicated after a few days. The authors rather feel that daily baths in normal saline solution with finger exercises is the procedure of choice. General care includes nutrition, correction of the loss of protein, oftentimes by means of extra feedings, plasma, blood glucose, amino acids and high vitamin intake. Sulfadiazine and penicillin are worthwhile adjuncts.

Oftentimes local conditions make a permanent repair ill advised and in these cases the authors believe that temporary skin grafting is of utmost value. In these cases they also object to small deep grafts and advise split thickness grafts. The disadvantages of making a permanent repair too early are that the marginal scar becomes hypertrophic, contracture of the scar tissue bed causes wrinkling of the graft and webbing occurs between the fingers which requires secondary operations to obtain a satisfactory result. Late skin grafting has the advantages of being an elective operation, complications can be reduced to a minimum, there is little or no chance of residual bacterial activity in the operative field and all scars can be removed down to the normal underlying tissues.

Late grafting of the burned dorsum of the hand closely follows the technique of other operations on the hand. Preparation the night before is directed toward cleaning and trimming the fingernails and scrubbing and soaking the hand. After this, the area is shaved. Repair is made with a tourniquet. A dermatome graft is secured. The scar tissue is removed and the graft is applied. When the burn has been deep enough to destroy bones and tendons, a

thick split graft is not adequate and a pedicled flap must be used. A one stage flap usually can be taken down in from 18 to 21 days tendons can be grafted beneath this and if necessary bone work can be done. These flaps should not be used distal to the metacarpophalangeal joints as they result in an unsightly and unwieldy finger. In certain cases capsulotomy is necessary.

The authors mention certain unsolved problems one of which is the distorted and destroyed finger nails. Their removal does not alter the shape while excision of the nail bed becomes painful whether it is covered with a graft or allowed to heal by scar. The second problem is the loss of an extensor tendon on the dorsum of the finger. Covering these fingers with a pedicled flap and then grafting tendons beneath the flap gives poor end results. The problem of circulation after burn is a blue and cold hand but the therapeutic possibilities of sympathectomy have not as yet been fully investigated. The fourth problem is one of matching color and this also has not as yet been satisfactorily solved. LOUIS T. BYARS, M.D.

Hecht, J. L. H.: *Reactions to Intravenously Administered Amino Acids (Casein Hydrolysates)*
Am J Med Sci, 1946 212 35

Hecht administered 550 infusions of 1.5 to 7 per cent amino acid (casein hydrolysate) solutions in 5 per cent dextrose in saline, 5 per cent dextrose in water or in normal saline, to 303 patients, in order to study the reactions. Pyrogenic activity had been excluded by testing the solutions on rabbits. The patients were chosen at random from the various services of the hospital except that only patients who had been free of fever for a period of at least 5 days were used. The total amount administered in one infusion (most subjects were given 2 infusions) was 500 c.c. and the speed of administration averaged 500 c.c. in one hour. In some cases serial determinations of blood amino acid levels were carried out before, during and after the infusions.

Reactions of some kind were observed in 7 per cent of the subjects and in 4 per cent of the infusions. There were no alarming reactions, nor any which resulted in long-lasting damage.

Fever and chills were present in 8 patients and were believed to be due to accidental contamination of the infusion set. This incidence appears to be no higher than that in comparable series of plasma or blood transfusions. Nausea, hot flushes, dizziness and vomiting occurred in 8 cases. The author suggests that these reactions may be due to fast infusion resulting in a rapid rise of blood amino acid levels, and there is reason to believe that some individual component of the amino acid mixture rather than the total amino acid level is responsible for such a reaction. Contrary to opinions of previous students of the subject liver damage seems not to favor the

occurrence of amino acid infusion reactions. The author makes certain recommendations which he believes may be helpful in reducing the incidence of unfavorable amino acid reactions (1) as amino acid dextrose mixtures are an excellent medium for bacterial growth they should be made up with the greatest of care by the physician himself and their preparation should not be left to the nursing staff (2) the mixture should be administered immediately after being made up (3) the rate of in flow should not exceed 15 c.c. of hydrolysate (= 100 c.c. parana mine ⁷) per hour (4) as prolonged parenteral feeding of amino acids will result in vein damage one should start with a vein on the dorsum manus and gradually move proximally with subsequent infusions.

HEINRICH LAMM M.D.

Altmeider W. A.: Acute Secondary Parotitis. *Surgery* 1946 20 19

During a period of 9 years, the author saw 49 patients with acute secondary parotitis. The average age of these patients was 47 5 years. The infection was of sudden onset during the course of a primary disease. The lesion was unilateral in the majority of cases and was accompanied by a sharp elevation of body temperature, pulse rate and white blood count. Purulent material obtained from the parotid abscess was monobacterial in 25 cases and polybacterial in 14 cases.

The plan of treatment consisted of the administration of from 120 to 250 minims of Lugol's solution per day. With improvement, the daily dose was decreased. When oral medication was not possible, Lugol's solution was given by hypodermoclysis along with physiological saline. The average dose of Lugol's solution was 833.4 minims administered over a period of 7 days. In every case an abscess, when present, was drained either before or during treatment. In 3 cases penicillin was used in conjunction with Lugol's solution and in 3 cases penicillin alone was used. In 43 cases treated with Lugol's solution resolution occurred in 59 and partial resolution with abscess in 5. In 6 cases, parotitis was in a state of resolution but the patient died of the primary disease. Signs of resolution only became manifest after a lag period of 36 to 48 hours and then the temperature and pulse rate began to decline and local clinical signs began to show improvement.

The use of penicillin alone for the treatment of secondary parotitis was also very encouraging. Although the mortality rate was 30.6 per cent it was noted that at the time of death the parotitis was in a state of resolution in all but 1 case.

The beneficial action of Lugol's solution is due to the bacteriostatic potency of iodine and its stimulation of the secretion of the salivary glands, thus inhibiting suppression of the parotid gland. Penicillin is an effective chemotherapeutic agent since this type of infection is pyogenic. In one case penicillin cleared up the parotitis where Lugol's solution had failed. The best results were obtained in early cases while the parotitis was in the diffuse inflammatory

state, before the onset of necrosis or abscess formation.

BENJAMIN G. P. SHAW, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Levenson, S. M., Adams, M. A., Green, R. W., Lind, C. C., and Taylor F. H. L.: Plasma Alpha Amino Nitrogen Levels in Patients with Thermal Burns. *N. England J. M.* 1946 335 467

The authors report on a study of the plasma amino nitrogen levels in 12 severely burned patients. In 8 of the 12 cases there was a significant elevation of the plasma amino nitrogen level but in none of the 12 cases was there a fall in the plasma level. In 7 of the 8 patients having an elevation of the alpha amino nitrogen level burns involving over 35 per cent of the body surface were present. Clinical shock was present in 7 of these 8 cases, while shock was present in only 1 of the 4 cases showing no elevation of the alpha amino nitrogen level. Of the 8 patients showing the elevation 7 had an elevation of the nonprotein nitrogen, however in all but 1 patient the rise in alpha amino nitrogen preceded the rise in the nonprotein nitrogen. The prothrombin time was prolonged in 4 of the 5 patients with elevated alpha amino nitrogen levels on whom determinations were made. On the other hand, there was no prolongation of the prothrombin time in the 3 patients having no elevation of the alpha amino nitrogen on whom the determinations were made.

The authors conclude that there is a close correlation between the elevation of the plasma alpha amino nitrogen concentration, the extent of the burn, the degree of the shock, and the prolongation of the prothrombin time.

It is probable that the rise in alpha amino nitrogen is the result of 2 factors, the increased rate of nitrogen metabolism and the decrease in liver function.

Lockwood, J. S.: Wartime Activities of the National Research Council and its Committee on Medical Research, with Particular Reference to Team Work on Studies of Wounds and Burns. *Ann. Surg.* 1946, 124 3-4

The mobilization of civilian research for meeting the special problems of military medicine and surgery by the Surgeons General of the Army and Navy in 1940 is described herein.

The Committee on Surgery of the National Research Council held its first meeting on June 15, 1940, under the leadership of Evans Graham. Thirteen subcommittees were organized on surgical infections, neurosurgery plastic and maxillofacial surgery thoracic surgery anesthesia, radiology orthopedic surgery burns, ophthalmology otolaryngology physical therapy urology, and vascular injuries. The subcommittees on surgical infections and burns were combined in December 1943 to form the subcommittee on infected wounds and burns, under the chairmanship of Allen O. Whipple.

The main purpose of this article is to review in broad outline the program of research which was conducted under the advice and sponsorship of the subcommittee, and to present an historical account of a unique experiment in co-operative surgical research on a national basis.

The three main functions served by the National Research Council Committees were to provide opportunities for informal exchange of experience between men with similar problems and interests from civilian life and from the armed services; to draft formal recommendations upon request of the armed forces or other governmental agencies; and to sponsor and review proposals for contracts submitted to the Committee on Medical Research.

Some of the subjects of the C. M. R. contracts for research in the surgical field investigated were the prevention and treatment of surgical infections 26 contracts studies on the pathology physiology and treatment of burns 19 contracts statistical analysis of wound and burn studies 1 contract orthopedic problems and prosthetic devices 8 contracts cold injury (including frostbite and trench foot) 6 contracts anesthesia and pulmonary physiology 2 contracts peripheral nerve repair 14 contracts concussion 10 contracts absorbable hemostatic cellulose 1 contract collagen sutures 2 contracts wound ballistics 2 contracts plastic surgery 4 contracts ophthalmology 4 contracts radiology 3 contracts vascular surgery 31 contracts and protein loss in lung surgery 1 contract.

The subcommittee on surgical infections at its initial meeting in June, 1940 began to make plans for a comprehensive study of chemotherapy in the control of infection in wounds. Chemotherapy, in the most recent bulletin on wound management from the office of the Surgeon General, U.S.A. indicates that the final evolution of prophylactic chemotherapy under combat conditions was not dissimilar from that obtained through the civilian study.

Chemotherapy No presently available chemotherapeutic agent can sterilize a contaminated or infected war wound. Neither penicillin nor the sulfonamides can prevent the ultimate septic decomposition of dead tissue or contaminated blood clots. Sulfonamides administered systematically are effective in the prevention and control of invasive hemolytic streptococcal infection but are ineffective in the control of staphylococcal or invasive clostridial infections. Penicillin is effective against hemolytic streptococci and staphylococci and in addition prevents the spread of clostridial infection from a focus of affected tissue. The effectiveness and limitations of chemotherapy are established sufficiently to attribute poor results to errors in surgical technique or judgment, rather than to drug failures.

a. The concomitant use of sulfonamides and penicillin is unnecessary. The use of sulfonamides as a supplement to penicillin therapy contributes only the risk of untoward reactions and complications. There is no clinical evidence of synergism with the two agents.

b. The routine local use of chemotherapeutic agents has been abandoned. Penicillin may be instilled into serous cavities or major joints to complement the initial or subsequent surgical management of injuries in these regions. Repeated dressings solely for the purpose of application of antibacterial agents contribute to persistent wound infection and suppuration with aerobic wound pathogens.

c. Systemic chemotherapy is an adjuvant to the surgical management of a contaminated or infected wound. It does not offset the hazard of residual dead space or improper drainage.

During the second year of the operation of the wound study units there was a gradual transfer of emphasis from the problem of prevention of infection in accidental wounds to the problem of treatment of established infections with the same research units and personnel, but with the addition of special units in large civilian hospitals. It had become apparent that the staphylococcus aureus resisted the action of sulfonamides. By January of 1943 penicillin became available in adequate amounts for research in special units. As a result of this successful venture in Army research the basic principles regarding the selection of cases, dosage indications for combined surgical treatment and the limitations of the drug could be published.

The evolution of burn treatment during the war led to the gradual abandonment of tanning methods and the substitution of a local treatment consisting in the application of a bland padded pressure dressing and the principle of treating the burn like any other large open wound. Early surgical excision and grafting proved feasible if the burn was of limited extent and if ample quantities of blood were transfused into the patient at the time of operation. However, the most promising technique for general use in third-degree burns appeared to be the employment of the padded pressure dressings of pyruvic acid in starch paste. When the burn slough can be entirely removed in 10 or 12 days after the injury by this method, which is usually the case, complete coverage by skin grafts can be accomplished early and the prolonged phase of suppuration and protein loss is avoided. The further destruction of islands of epithelium through infection is prevented and the development of scar tissue and contracture is minimized.

A large amount of work was carried on in many centers on the physiological aspects of burn treatment with regard to the imbalances in fluid electrolytes plasma protein, hemoglobin nitrogen and vitamins which accompany the severe burn.

JOHN H. MOHARDT, M.D.

Florey, M. E., Turton, E. C. and Duthie, E. S. Penicillin in Wound Exudates. *Lancet* Lond. 1945 2 405

The routine prophylactic injection of 100,000 units of penicillin intramuscularly in severe battle casualties prompted the investigation of the penicillin content of the wound exudates, blood and

urine after such an injection. After this the effect of the same dose when instilled locally into the wound was determined.

A technical problem was encountered in the process of assaying the penicillin concentration of the wound exudates. It was found that an inhibitory factor other than penicillin was present in some exudates; some wound exudates inhibited the test staphylococcus even when incubated with penicillinase.

Eleven patients with open wounds were given 100,000 units of penicillin intramuscularly. In every case there was an inhibitory concentration of penicillin in the wound exudate up to 8 hours after the injection, and in 50 per cent of the cases inhibitory concentrations were present 24 hours after the injection. The blood penicillin level fell more rapidly; all cases showed detectable penicillin in the blood up to 4 hours, and 50 per cent of the cases showed detectable levels up to 7 hours after the injection. The penicillin level was elevated for the longest time in the urine; all cases showed penicillin in the urine up to 20 hours, and 50 per cent of the cases up to 24 hours. Thus following intramuscular injection, penicillin disappears from the body fluids in the following order: first from the blood, next from the wound exudate and last from the urine.

The local instillation of 100,000 units of penicillin was then carried out on 8 separate wounds, all of which were over 9 days old, and 7 of which were infected with the *Bacillus coli*. The concentration of the penicillin instilled was 25,000 units per cubic centimeter. In every case there was an inhibitory concentration of penicillin in the wound exudate for 48 hours after the instillation, and in 50 per cent of the cases for from 60 to 72 hours. The blood penicillin levels following local instillation were the same as following intramuscular injections. All cases showed detectable blood penicillin for 4 hours and 50 per cent of the cases for 6 hours. Penicillin was detected in the urine in this group for at least 24 hours and in 50 per cent of the cases for 48 hours. Thus following local instillation, as long as penicillin is excreted in the urine inhibitory concentrations are present in the wound exudate.

Thus, penicillinase producing bacteria do not neutralize the effect of the drug in the wound. Furthermore, as a single intramuscular injection produces therapeutic levels in the wound exudate for from 8 to 12 hours, it may be quite feasible to treat purely local infection by a reduced number of injections in 24 hours. One or two injections in an aqueous solution may suffice without recourse to such vehicles as beeswax and peanut oil.

It was a striking fact that when local instillation of penicillin was performed inhibitory concentrations of penicillin were present in the blood for as long as after intramuscular injection and in the urine for twice as long. Thus, in view of its much greater local effect, the local implantation of penicillin in a wound will afford surer protection than intramuscular injection.

North, E. A., Christie, R., and Rank, B. K.: Penicillin Resistant Staphylococci in Wounds. A Report Based on a Study of 59 Cases of Infected War Wounds. *Med. J. Australia*, 1945, 2:43.

In an earlier investigation the authors discovered that 58 per cent of staphylococci cultured from open war wounds were resistant to penicillin. In the present study the biological and serological characteristics of the penicillin-resistant staphylococci were investigated.

A series of tests were performed for hemolysis a and b for coagulase for fibrinolysis, for mouse pathogenicity for mannitol fermentation, and for pigment formation.

Penicillinfast staphylococci were classified into 4 groups: group A, in which only penicillin-sensitive strains were isolated from wounds; group B in which penicillin-sensitive strains followed by penicillin-resistant strains were isolated; group C, in which only penicillin-resistant strains were isolated; and group D in which a mixture of both types of strains were cultured. The organisms of groups B, C, and D were obtained from complicated war wounds in which there was delayed healing.

There was no evidence to indicate that retarded wound healing was due to the presence of penicillin-resistant staphylococci. Rather it was claimed that wounds healed only after surgical methods converted them into simple uncomplicated tissue wounds. Healing was independent of antibiotic treatment or bacteriological sterilization. The staphylococci cultured from wounds classified in groups B, C, and D were of types III, VI, and VIII serologically. These were not obtained from group A organisms.

In 17 out of 30 cases, nose and throat swabs revealed the same strains as were previously identified in the wounds. The authors were never able to demonstrate intermediate strains in those cases in which transition occurred from the penicillin-sensitive state to that of the penicillin-resistant state. It may be hypothesized that the penicillin-resistant strains became dominant as a result of the elimination of the sensitive strains during the course of penicillin therapy, or that wounds became contaminated from self-infection or cross infection. The first assumption should be eliminated since initial cultures failed to show evidence of the production of penicillinase. The possibility of self contamination cannot be denied as a result of the authors' findings. The latter has also been corroborated by Miles and others, who showed that 50 per cent of normal adults were carriers of *Staphylococcus aureus* in the nose, and an additional 25 per cent carried this organism on the skin of the wrist.

Until other studies are completed it is suggested that the high incidence of penicillin-resistant staphylococci be accounted for on the basis of stimulation from penicillin therapy as a result of which a transformation or mutation of the penicillin-resistant variety of bacteria developed in wounds.

ANESTHESIA

Estes, B., and Hinrich H. E.: *Stages and Signs of Pentothal Anesthesia*; *Physiological Basis of Anesthesiology* 1946 7 536.

A discussion is given of the physiological basis for the classification of the stages and clinical signs of pentothal anesthesia, and a correlation is made between the degree of cerebral metabolic inhibition and the various anesthetic stages. The physiological basis is divided into two parts (1) the symptoms and signs allocated to each layer of the normal unanesthetized brain and (2) an examination of the metabolic rates of the various parts of the brain as well as the influence of barbiturates upon the brain metabolism.

It was found that in every instance pentothal anesthesia induced a depression of the cerebral metabolic rate and in a characteristic manner cerebral oxidations are depressed earlier and more definitely than those of the rest of the brain. This depression is a progressively descending phenomenon which may finally envelop the entire brain.

Continuous drip pentothal anesthesia and intermittent pentothal anesthesia were used to obtain deepening anesthesia. The eyelid size of the pupils reflexes, and resistance to various types of painful stimulation were observed during the resting state and during the various stages of anesthesia. Cerebral blood flow determinations were made according to the method of Ketty and Schmidt. The cerebral blood flow when multiplied by the cerebral arteriovenous oxygen difference yielded the cerebral metabolic rate. It was found that in most instances the clinical signs of pentothal anesthesia are related to the metabolic inhibition and may be segregated into 4 stages conforming in general to a definite pattern.

The first stage is that of clouded consciousness. The highest phylic layer the cerebral cortex, is moderately depressed throughout this stage and euphoria is a characteristic manifestation. The second stage is that of hypersensitivity which begins with the loss of consciousness. The functions of the cerebral cortex are suppressed and the second layer is the highest one remaining in function although it is under slight depression, particularly with regard to the hypothalamic activities and those of the subcortical motor nuclei.

The third stage is that of surgical anesthesia and is divided into 3 planes—light, moderate, and deep. They are characterized by alterations in responses as well as to changes in the eyeball movements. The first plane of light surgical anesthesia begins with a diminution in response to painful stimulation. At this point not only are the cerebral hemispheres suppressed deeper than in the second stage but is still functional. The second plane of moderate surgical anesthesia is characterized by the abolition of muscular response to painful stimulation, but pupillary

dilatation and respiratory changes are still evoked. Here the midbrain, although somewhat depressed still acts as the highest remaining functional level. The third plane of deep surgical anesthesia is characterized by loss of pupillary and respiratory reactions to various stimuli because the lowest pain center becomes increasingly depressed with the other mid brain mechanisms.

The fourth stage is that of impending failure and is characterized by signs of extreme depression of respiration, diminution of pulse pressure, and onset of pupillary dilatation due to anoxia. In this stage the pons and medulla are the highest active cerebral regions.

The evolution of the signs of clinical significance is summarized in a chart. The pupil constricts in the second and third planes of the third stage. The pupillary reaction to light disappears in the second plane of the third stage when the Edinger Westphal nucleus is obtunded. The eyeball movement becomes fixed and centrally placed in the second plane of the third stage. The corneal reflex shows great variability but may disappear in the second stage or in the first and second planes of the third stage. A discussion is given of the effect of the drug on respiration throughout the 4 stages.

Thus, it has been shown that the stages of pentothal anesthesia produce signs which represent a descending neuroanatomic allocation with deepening anesthesia. The earliest clinical changes are associated with the lower phylic areas of the brain. This conclusion drawn from clinical observations receives support from cerebral metabolic studies.

Barbiturates depress brain metabolism but the role played by them is not the entire story. Observations made both on animals and man reveal that some of the clinical signs are out of proportion to the depth of anesthesia. Electroencephalogram studies show that sensory impulses reach the cerebral hemispheres but motor expression is preferentially depressed with barbiturates. The barbiturates have a specific effect in interfering with the activity of the hypothalamus.

The pattern of pentothal anesthesia is the result of a 2 fold mechanism, a descending depression of the cerebral oxidations starting with the cerebral hemispheres and extending to and including the lower parts of the brain and a specific effect on nerve function exerted in certain cerebral areas.

MARY KARP M.D.

Johnson, K., and Gilbert C. R. A.: *Intravenous Procaine for Obstetrical Anesthesia*. *Current Res Anesth.* 1946, 35 133

Twenty obstetrical patients were given intravenous procaine for analgesia and anesthesia, and the results are recorded in this article. Two types of continuous procaine infusion for relief of various surgical pains are recommended. In the first, the dosage is such that normal consciousness and other functions are undisturbed for indefinite periods. In the second a state of semiconsciousness or uncon-

sciousness is obtained in which all pain is abolished. In this latter stage the only complication encountered was the occurrence or threat of convulsions in a small minority of cases. This was remedied by the intravenous administration of a barbiturate such as sodium luminal or sodium amylal or by the administration of nembutal before the procaine infusion was started.

A 1 per cent solution of procaine diluted in 5 per cent glucose solution was used in all instances. Tests were made for procaine sensitivity by injecting a drop of a per cent solution intradermally and waiting 15 minutes for a reaction. Upon a negative result a drop was then instilled in one eye for further verification.

The 30 cases are described as case reports and added to the 12 previously reported, make up a series of 38 cases without a death or serious accident. The amount of procaine administered varied from 0.4 to 0.7 gm. The simplicity of the method makes it available for every physician and makes it feasible in an environment in which caudal and other complicated anesthetic methods are not available. If the hopes concerning both the efficiency and safety of the procaine method are fulfilled by further careful experience it may be an important and practical procedure for the relief of pain in childbirth.

MARY KARP M.D.

Gordh, T., and Rydin H.: The Question of Cerium Oxalate as a Prophylactic against Postoperative Vomiting. *Anaesthesiology* 1946, 7: 326.

Cerium oxalate has been used in medicine since the middle of the last century as a prophylactic against vomiting from different causes. There are also some reports of very favorable results from the use of cerium oxalate as a prophylactic against postoperative vomiting.

The literature contains at least 70 reports of the good therapeutic effect of cerium oxalate compounds against vomiting in such cases as those mentioned whereas only a few isolated investigations have produced negative results.

In the course of the last few years a comparatively extensive advertising campaign has been carried on in favor of the use of cerium oxalate for different kinds of vomitings.

Various explanations of the supposed anti-emetic effect of cerium oxalate have been reported. When administered by mouth, cerium oxalate is said to affect the mucosa of the stomach and intestine locally similar to an astringent, or after the resorption of small amounts, to reduce the reflex excitability and thus lessen the state of irritability of the mucosa. After resorption from the intestinal mucosa, or on parenteral administration, the effect is explained as the result of a more central action the cerium oxalate being an elective agent for mitigating parasympathetic states of irritation. As shown by the following survey of the literature, however the pharmacodynamic and therapeutic effects are questioned or repudiated in reliable textbooks.

The investigation was carried out in surgical out-patient departments of hospitals in Stockholm, Sweden, both peroral and intramuscular administration of cerium oxalate being tested as a prophylactic against postoperative vomiting. No other medications were administered. The anesthetics were administered by interns and students under the supervision of the resident anesthetist or the surgeon.

In the first series, every other patient who was to be subjected to some operation requiring ethyl chloride anesthesia or ethyl chloride plus ether narcosis received 30 to 30 minutes before operation, 2.5 gm. of cerium oxalate by mouth in the form of 5 tablets which were called "cerolets A." Alternate patients received the same number of control tablets, called cerolets B, consisting merely of indifferent ingredients. Neither the physicians nor the hospital staff was informed that in some cases the tablet contained merely inactive ingredients.

In series 2 which was carried out a few months after the termination of the tablet series, exactly the same procedure was adopted, with the following exceptions. Instead of peroral administration of cerium oxalate and indifferent control tablets, respectively every other patient received intramuscularly 1 ml. of "peremexin A," containing 0.05 g. of cerium oxalate in a colloidal form, and alternate patients received 1 ml. of "peremexin B," containing merely physiological saline solution, with the addition of fluorescein to obtain the same color.

Of the 82 patients who had received cerium oxalate by mouth 19 (23 per cent) showed effects of the narcosis in the form of either vomiting or nausea, or both. Vomiting occurred in 16 per cent of the patients. Of the 83 controls who received sham tablets, 29 per cent had effects, most of them (20 per cent) in the form of vomiting. No difference was observed between the patients who were given cerium oxalate for prophylactic purposes and those who received control tablets with merely indifferent ingredients, either in the number of patients who showed effects of narcosis or in the nature of these effects. No difference in these respects was observed between the 32 patients who were treated with cerium oxalate intramuscularly and the 35 controls who received the same amount of physiological saline solution. In the first mentioned group, 19 per cent of the patients showed some reaction. In the controls, 14 per cent were affected.

Thus, contrary to the previously cited reports in the literature the authors could not observe any prophylactic effect of the cerium oxalate on vomiting resulting from narcosis before operation.

MARY FRANCES POE, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Jenkins, H. P., Janda, R., and Clarke, J.: Clinical and Experimental Observations on the Use of Gelatin Sponge or Foam. *Surgery* 1946, 60: 14.

The development of absorbable hemostatic agents has been an important recent advance in surgical

technique. The use of fibrin foam and oxidized or soluble cellulose has been well presented in several recent reports. A third hemostatic substance is gelatin sponge or foam.

In a previous article the authors reported on the absorbability of gelatin sponge. It was found to undergo absorption within 5 weeks, when implanted in the liver kidneys spleen omentum or abdominal wall. The tissue response was nominal or minimal as compared with the reaction to absorbable suture material. Subsequent to its absorption no residual inflammatory reaction was present.

Thirty dogs were subjected to laparotomy and wounds of various sizes and types were made in the liver kidneys or spleen. The gelatin sponge was moistened in saline and applied with pressure. Hemostasis was effective. The wounds varied in size from deep scalpel incisions to resection of a portion of a lobe of the liver. Within one-half hour the sponge was so adherent that it was often difficult to remove without tearing. These experiments were done for the most part without the addition of thrombin with the addition of thrombin there appeared to be a more rapid hemostatic action.

Control studies were made with the use of soluble cellulose and fibrin foam. The immediate hemostatic action of the three substances appeared to be approximately the same. The animals were sacrificed at varying periods of time no evidence of secondary hemorrhage was present and complete absorption

was found to be present in a number of instances within from 2 to 3 weeks.

The gelatin sponge was used in 60 patients. It was used to control the bleeding from the raw surface left after removal of the gall bladder in liver biopsies, to control difficult mesenteric bleeding and was particularly valuable in the control of very troublesome bleeding from the under surface of the diaphragm following splenectomy. When used in subtotal thyroidectomies it appeared to cause a somewhat excessive serum accumulation. When used as a rectal pack following hemorrhoidectomies and fistulectomies it was rapidly liquefied and obviated the necessity for a removable pack. This was in contrast to the soluble cellulose which when used in the rectum hardened and had to be removed with difficulty. The gelatin sponge was also used as a vehicle for the application of penicillin locally to granulating wounds, with satisfactory results.

Thus the gelatin sponge has, of itself, marked hemostatic properties which the authors believe is augmented by the addition of thrombin. Thrombin cannot be used with soluble cellulose. Where a large number of ligatures are concentrated in a small area, as in a thyroidectomy this agent should be used with caution in view of the apparent increase in a tendency for serum accumulation in wounds. Gelatin sponge appears to have many useful possibilities in the problems of hemostasis in general surgery.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Brown S. and Harper, F. G.: A New Roentgen Sign in Extrahepatic Biliary Tract Disease. *Radiol* 1946 47 39.

The authors previously called attention to a new roentgen sign which can be utilized to advantage in the diagnosis of extrahepatic biliary tract disease. Since then many more cases were observed and it was found that the sign is also useful in the differential diagnosis between obstructive and nonobstructive jaundice being present in the former and absent in the latter.

This sign consists of a pressure defect which is produced in the contour of the superior flexure of the duodenum by the dilated extrahepatic biliary tract.

A study of the normal anatomic relationship of the duodenum and the neighboring structures shows that the superior flexure of the duodenum is surrounded by the neck of the gall bladder on the right side, the cystic and hepatic ducts above, and the common duct on the left side. Thus the duodenum is practically encircled by an almost closed ring which is further reinforced by the solid structures of the liver and the pancreas above and below. When the biliary ducts of this ring are expanded by an obstruction due to a stone or tumor within the tubular system or by an extrinsic mass in the vicinity of the duodenum a pressure effect upon the enclosed fixed

duodenal segment develops. This pressure effect, however, cannot be demonstrated roentgenologically in the usual posteroanterior view since the course of the superior flexure of the duodenum is from before backward. The authors found that a right lateral decubitus position permits the visualization of the entire configuration of the duodenal loop. In this view most alterations in position, shape, and contour resulting from intrinsic or extrinsic changes are easily recognizable.

Twelve cases in which the method proved of value are briefly presented and the respective roentgenograms are reproduced for the purpose of illustration. T. LUTUNA, M.D.

Hinkel, C. L., and Nichols, R. L.: Opaque Myelography in Penetrating Wounds of the Spinal Canal. *Am. J. Roentg* 1946, 55 669.

The authors present a report of 13 cases in which myelography and surgery were carried out following penetrating wounds of the spinal canal. The roentgen findings are reviewed and correlated with the surgical findings. The categories of defects found in the myelograms are classified for the purpose of discussion.

1. Clearly margined indentations. A sharply margined, localized, clearly outlined indentation of the oil column indicates localized external pressure on an intact dura. The defect is almost identical

Fig. (Hinkel and Nichols) Example of clear cut, sharply margined indentation. a, the bullet is in the muscles of the back. Arrows indicate multiple hair line fractures of the left lamina of L4 and left transverse process. b, anteroposterior view of oil showing defect opposite fractured lamina at level of the disc between L4 and L5. c, lateral view. Patient prone. There is no ventral indentation of the oil column. Note that the oil does not outline the dorsal margin of the neural canal in the prone position.

Fig. 2.

Fig. 3a.

Fig. 3b.

Fig. 2. Compression of bone fragments. Supine left posterior oblique view shows an oil puddle at T5 and 6, and narrowing of the column at T7 and 8.

Fig. 3. a. The oil column angulates to the left at the site of the metal fragment. The nerve root on the right was severed. b, prone lateral view. The metal fragment is buried in the body of L5. At L1 and L2 the oil is in apposition to the vertebral bodies but at L3 and L4 the oil is displaced backward several millimeters (arrows). Operation revealed an abscess about the foreign body and a large organising hematoma ventral to the dura at L3 and L4 (arrows).

with the well known defect produced by uncomplicated posterior or lateral protrusion of the intervertebral disc but not necessarily at a disc level. It may be dorsally ventrally or laterally located. This type of defect in the present series was always found associated with fractures and loose bone chips from laminae or one pedicle.

2 Angulation. Angulation of the column requires no definition. It is readily recognised following some through-and-through wound of the dura. The defect, the authors believe is the result of scarring and contraction of the dura and epidural soft tissues in the axis of the missile tract. Another factor in the production of angulation is traumatic unilateral severance of the nerve roots and dentate ligament which normally stabilise the dural tube.

3 Extra-arachnoid oil (near the lesion). Extra-arachnoid oil fills a diverticulum or a short sinus, the long axis of which is parallel with that of the neural canal. This defect should not be confused with faulty injection of extra-arachnoid oil. The above are attributed to the remaining defects from healing tears of the meninges.

4 Displacement of the column of oil. Displacement of the column of oil is occasionally encountered. The arachnoid contents may be displaced either ventrally or dorsally for several millimeters by any thing (usually semifluid) which fills the subdural or epidural spaces in a "layered" manner. The oil column is found to be farther from the bony wall of the neural canal than normal.

5 Feathery irregular filling defects (localised partial obliteration of the subarachnoid space). Frequently because of localised obliteration of the subarachnoid space the oil is prevented from distributing itself evenly or completely about the spinal cord or the fibers of the cauda equina. This uneven spread of the oil produces very striking abnormalities in the myelographic picture. The myelographic appearance is that of single or multiple irregular "feathery" filling defects within the oil column.

6 Altered physical characteristics of the oil. When pantopaque fails to remain in a column or disperses into fine droplets there is found an alteration in the cerebrospinal fluid.

7 Complete subarachnoid block. The myelographic appearance is variable the oil column may taper to a point before stopping or may terminate in a ragged oblique or transverse manner. Anatomically subarachnoid block is obliteration of the subarachnoid space surrounding the cord or filaments of the cauda equina. It may be produced by (a) extrinsic pressure, (b) intrinsic pressure (c) active inflammatory process or (d) scarring as the result of very extensive destruction of nerve tissue.

The authors believe that myelography with possibly some modification should be undertaken in every patient who exhibits neurological signs following a wound involving or suspected of involving the neural canal. The routine myelographic technique must be varied to meet the problem of the patient with a cord injury. After examination the opaque

medium is removed under roentgenoscopic control. Opaque myelography greatly facilitates the establishment of an anatomical diagnosis in spinal injuries. It may reveal a residual remediable lesion even after presumably thorough surgical exploration or lesions which simulate actual destruction of nerve tissue such as extradural abscesses, hematomas, displaced bone fragments or pia-arachnoiditis, which are surgically remediable. FRANK L. HURSEY, M.D.

Murphy, F. Pascucci, L. M., Meade, W. H., and Van Zwailenburg, B. R.: Myelography in Patients with Ruptured Cervical Intervertebral Discs. *Am. J. Roentg.* 1946, 56: 27

From January 1, 1943 to July 1, 1945 the authors performed 62 pantopaque myelograms of the cervical spine. They were done only after plain films of the spine were taken first. These preliminary films showed abnormal findings in 88 per cent of cases in which the subsequent myelograms were positive for disc lesion and in 52 per cent of the cases with negative myelograms. The following abnormal findings were searched for on these films: scoliosis, straightening or reversal of the normal cervical curve, calcification in the posterior joint space, encroachment of the intervertebral foramen by soft tissue shadow and/or osteophyte and localized arthrosis. Most significant of these findings was the abnormal curvature of the cervical spine. However the authors were aware of the fact that there are other—more frequent—causes for this finding than rupture of the cervical intervertebral disc. Next in importance (with reference to disc lesions) seemed the presence of localised osteoarthritic spur formation.

The myelographic procedure consisted of fluoroscopy and the taking of spot films in the prone and oblique positions. (Lateral films were found to be of little value.) The more common findings encountered were deviation in the direction of flow, delay of passage, and filling defects.

The correlation of the myelographic to the operative findings was as follows:

	Myelogram positive	Myelogram negative
Operation with positive results	17 ¹	0
Operation with negative results	0	3
No operation	11	31
Total	28	34

¹Includes reoperations.

It is pointed out that the cases were carefully selected for operation on the basis of the clinical findings and that this high correlation is deceptive because of the many nonoperative cases and the impossibility of exploring cases regardless of the findings and indications for surgery.

The distribution of lesions observed myelographically was as follows:

A. Side	Cases	Percent
Right	21	56
Left	7	44
Total	28	100

B. Level	Cases	Percent
C3	2	7
C4	1	3
C5	12	33
C6	21	56
C7	2	5

The authors conclude that rupture of the nucleus pulposus in the cervical region is relatively common, especially in the lower section where the stress upon the spine is similar to that in the lumbosacral region. The diagnosis can be made clinically in many cases. Plain films of the cervical spine are helpful. Positive myelographic findings proved highly accurate in the small series of operative cases. The significance of negative myelograms in the cervical region is not yet established but is probably greater than that of those in the lumbar region.

The technique of this procedure, which includes prophylactic chemotherapy and asepsis in case of the measures commonly employed in spinal punctures, is described. GEORGE S. SCHWARTZ, M.D.

Maltby, G. L., and Pendergrass, R. G.: Pantopaque Myelography: Diagnostic Errors and Review of Cases. *Radiology* 1946, 47: 15

The experience of the authors with 115 pantopaque myelograms, 69 of which were followed by operation is reported.

From 3 to 6 c.c. of pantopaque were injected. If the needle was inserted over what appeared to be a lesion, it was withdrawn and the examination was continued. The table had to allow for at least a 30 degree Trendelenburg tilt in one direction and an upright position of the patient in the other extreme excursion. At least two spot films were taken of any suspicious area to insure constancy of the finding. The patient was rolled onto both of his sides in order to avoid false nonfilling of the root canals. The important filling of the caudal sac was insured by placing the patient into the upright position and occasionally by having him perform the Valsalva maneuver. Oblique views were found helpful. The contrast material was removed after the examination. The final x-ray diagnosis was made only after a conference with the neurosurgeon in each case.

The findings were as follows: of 107 patients with positive myelograms 57 (53%) were operated upon. Of these 57 (80.4%) showed a disc lesion at operation. Exploration was negative in 6 patients (10.6%). Nine patients in whom the x-ray findings were negative were operated upon because of what seemed to be classical clinical findings of a ruptured disc. In 5 (56%) of these 9 patients the findings on exploration were negative, while in 4 (44%) a definite rupture of the nucleus pulposus was observed.

Eight myelograms showed positive findings not frankly characteristic of a ruptured disc. The following x ray diagnoses were made in these cases: myelograms suspicious of ruptured disc but needing clinical confirmation 3; arachnoiditis 1; postoperative scar tissue 1; unsatisfactory, because of extra-arachnoid oil 1; multiple filling defects cause unknown, 1; and block 1. Of the 8 patients 3 came to operation. In the case labeled "postoperative scar tissue" a recurrent disc was found. The one diagnosed simply as "block" showed a small epidural abscess and the one considered as "roentgenologically suspicious of a disc but needing clinical confirmation" showed a ruptured disc.

The authors arrive at the following conclusions: Positive myelographic findings without the usual appearance found in disc protrusion can be caused by extra-arachnoid injection of oil, centrally protruded disc, arachnoid block caused by disc lesion or arachnoiditis varices, adhesions and epidural abscess. A negative myelogram may result despite the presence of a disc prolapse when the column of contrast material is too narrow.

GERHART S. SCHWARTZ, M.D.

Klein, I.: Treatment of Peritendinitis Calcarea of the Shoulder Joint by Roentgen Irradiation; Report of 100 Cases. *Am J Roentg* 1946 56 366

One hundred cases of peritendinitis calcarea of the shoulder were treated with x rays between 1937 and

1945. The cases were divided into 61 acute (duration of symptoms under 1 month) 11 subacute (of 1 to 3 months' duration) and 28 chronic (duration over 3 months). All shoulders were subjected to roentgenography before the treatment. The absence of visible calcifications in the first group was no contraindication to x ray treatments. In this group there was partial or complete resolution of the visible calcium following treatment in 69 per cent of the cases. In the second group this figure was only 36 per cent and in the third group only 32 per cent.

The results were best in the first group in which relief from pain was achieved usually within a few days after the treatments were started. The average disability period (counted from the onset of treatment) was as follows: group I 8.5 days; group II 26 days; and group III, 36 days.

Three cases were referred to surgery. In 1 case which did not respond to x ray treatments operation revealed an osteochondroma as the source of the roentgenographic density in the shoulder.

One treatment course consisted usually of from 6 to 8 treatments of 125 r average each administered within from 7 to 14 days over the affected shoulder region (in part posteriorly and in part, anteriorly) with kV 125 to 200 target-skin distance from 30 to 40 cm. ma. from 5 to 7 and field size 10 by 15 cm. Patients of group I received 1 course; those of the other groups usually 2 courses.

GERHART S. SCHWARTZ, M.D.

medium is removed under roentgenoscopic control. Opaque myelography greatly facilitates the establishment of an anatomical diagnosis in spinal injuries. It may reveal a residual remediable lesion even after presumably thorough surgical exploration, or lesions which simulate actual destruction of nerve tissue such as extradural abscesses, hematomas, displaced bone fragments, or pia-arachnoiditis, which are surgically remediable. FRANK L. HURLEY, M.D.

Murphy, F., Pascucci, L. M., Meade, W. H., and Van Zwailunburg, B. R.: Myelography in Patients with Ruptured Cervical Intervertebral Discs. *Am. J. Roentg.* 946, 56-57

From January 1, 1943 to July 1, 1945 the authors performed 62 pantopaque myelograms of the cervical spine. They were done only after plain films of the spine were taken first. These preliminary films showed abnormal findings in 88 per cent of cases in which the subsequent myelograms were positive for disc lesion and in 52 per cent of the cases with negative myelograms. The following abnormal findings were searched for on these films: scoliosis, straightening or reversal of the normal cervical curve, calcification in the posterior joint space, encroachment of the intervertebral foramen by soft tissue shadow and/or osteophyte and localized arthrosis. Most significant of these findings was the abnormal curvature of the cervical spine. However the authors were aware of the fact that there are other—more frequent—causes for this finding than rupture of the cervical intervertebral disc. Next in importance (with reference to disc lesions) seemed the presence of localized osteoarthritic spur formation.

The myelographic procedure consisted of fluoroscopy and the taking of spot films in the prone and oblique positions. (Lateral films were found to be of little value.) The more common findings encountered were deviation in the direction of flow, delay of passage and filling defects.

The correlation of the myelographic to the operative findings was as follows:

	Myelogram positive	Myelogram negative
Operation with positive results	7 ¹	0
Operation with negative results	0	3
No operation	1	3
Total	8 ¹	34

¹Had been reoperated.

It is pointed out that the cases were carefully selected for operation on the basis of the clinical findings and that this high correlation is deceptive because of the many nonoperative cases and the impossibility of exploring cases regardless of the findings and indications for surgery.

The distribution of lesions observed myelographically was as follows:

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

McFarlane, R. G., and O'Brien, J. R.: The Relation of the Blood Sedimentation Rate. *Proc. R. Soc. Med.*, 1946, 157.

In 1921 Fåhræus first made a practical application of the sedimentation phenomenon by adding anti-coagulant to blood to keep it fluid. With the use of a simple technique he established the range of normal limits and the variations found in disease. Since 1 c.c. of packed red cells weighs about 1.09 grams and a similar volume of plasma weighs only about 1.03 grams, the red cells will naturally sink in plasma. If the cells remain discrete they fall slowly but in certain cases they clump together to form rouleaux in which hundreds or even thousands of cells are packed into a solid mass. The larger the mass is the faster it will fall. For every cell that falls, an equal volume of plasma is displaced upward. Thus the cells fall through an upward current of fluid which slows their fall. The greater the number of cells in a given volume of blood the greater will be the upward flow of displaced fluid and the greater its retarding effect on sedimentation. This factor assumes considerable importance in dealing with the varying red cell counts found in disease.

The formation of rouleaux is the major factor in sedimentation and is the actual index of abnormality. Red cells in blood normally remain separate. However in certain conditions the cells become regularly arranged into columns, or rouleaux, which in turn may adhere to each other to form masses. The cause of rouleaux formation seems to lie in the plasma surrounding the red cells rather than in the cells themselves. Cells from a blood sample showing a high sedimentation rate, if washed free of their plasma and suspended in normal plasma, will show no excessive rouleaux formation. Cells from the normal blood will form rouleaux in the abnormal plasma. No specific substance analogous to an agglutinin, can be shown to exist in the abnormal plasma. The tendency of any plasma to form rouleaux seems to be determined by the balance of its "active" and inhibitory proteins. Fibrinogen and euglobulin are the most active proteins. An albumin fraction (globuloglycoid) and nucleoprotein are the most inhibitory. Other fractions are intermediate or neutral in action. Abnormal proteins may be present in plasma as in myelomatosis, and increase the sedimentation rate. Alterations of the balance of plasma proteins tending to increase rouleaux formation and hence the sedimentation rate are liable to occur in any condition involving infection or destruction of tissue.

Several technical factors influence the sedimentation rate. The anticoagulant used should not produce dilution. Blood should be tested within 4 hours

of its withdrawal, for after this period of time its sedimentation decreases. The tube used should be at least 200 millimeters long to minimize the decelerating effect which packing of the cells has on their rate of fall. Its diameter should not be less than 2 millimeters. It should be kept absolutely upright. Before being tested blood samples should be thoroughly agitated, by shaking them for at least 2 minutes, to break up rouleaux already formed.

In sedimentation there are three distinct phases. First, there is a period of about 15 minutes during which aggregation of rouleaux is occurring. Then more rapid sedimentation occurs, at an apparently constant rate. The duration of this period of free fall is determined by the length of the tube. In the third phase the packing of the cells on the bottom of the tube slows the sedimentation until finally it ceases.

The rate of sedimentation can be measured in at least three ways. The time required for cells to fall a given distance may be measured. The sedimentation may be measured at the end of an arbitrary length of time, usually an hour. Or readings may be taken at 5 minute intervals, to avoid the errors introduced by aggregation and packing and arrive at a true maximal rate of fall per minute.

The most important intrinsic factor influencing the sedimentation rate is anemia. In simple acute anemia the cells, reduced in number for a given volume of plasma, fall more rapidly. However it has been found that in chronic anemias a natural compensatory mechanism reduces the capacity of the plasma to form rouleaux. This has minimized the value of Wintrobe's correction chart. Some of the difficulties in evaluating anemic blood samples may be eliminated by reconstituting the blood (by centrifuging, removing an appropriate amount of plasma, and remixing) to a normal packed cell volume before making observations. Other intrinsic factors affecting sedimentation are the size and shape of the red cells. Variations in cell size, seen in pernicious anemia and other liver factor deficiencies, prevent good rouleaux formation. The spherical cells of acholic jaundice and the varying forms in sickle cell anemia have very little tendency to form rouleaux. B F LOUGHEART M.D.

Murray G. Simpson, J. S., and Watters, N. A.: Treatment of Extremities following Sudden Failure of Circulation. *Surgery* 1946, 20:15.

There is much evidence to indicate that the orthodox method of the treatment of acute failure of circulation such as occurs in embolism, diabetes, senile or Burger's gangrene, or injuries to major blood vessels and frostbite, might be revised to advantage.

With the present knowledge of physiology it would seem that the application of rational prin-

ciples might prevent the advance of a pregangrenous condition and might set up conditions which would favor a return of circulation and survival of the part. With impaired arterial flow into an extremity elevation beyond the horizontal position can easily set up conditions under which no blood may reach the periphery. Also in this posture the veins are emptied so that only the proximal capillaries of the extremity have any circulation of blood passing through them. Elevation and arterial spasm may prevent any blood from reaching the vascular tree beyond certain levels. Therefore, if the vascular tree is kept empty there is no available supply of oxygen and as each living cell has a limited number of hours that it can survive without oxygen necrosis and gangrene are inevitable. The absence of oxygen over a certain period causes changes in cells which are irreversible so that even should the circulation be restored, the blood that enters the affected area will clot rapidly and plug up the entire vascular tree which again completely deprives all cells of their oxygen supply and necrosis must be the end result. If an extremity is without blood and becomes desiccated it cannot possibly survive. If it is kept full of blood no matter how venous the blood may be provided it is not allowed to clot, there is some possibility of survival of the cells. If with the dependent position of the extremity cold is also applied, the requirement for oxygen can be cut down to the minimum and with good luck there may be sufficient circulation to provide the necessary oxygen. Intravenous heparin will prevent thrombosis in the peripheral vessels and under these conditions may be of considerable value.

Animal experiments and a report of 3 cases indicate that in extremities with impaired circulation the best prospects for survival can be provided by keeping the extremity dependent by the application of cold and by using methods to effect maximum dilatation of the collateral vessels entering the extremities.

BENJAMIN GOLDMAN, M.D.

Keynes, G. Collins, D. H., Martin, P. Symonds, C., Laurent L. P. E., and Sandifer P. H.: Symposium on the Surgical Treatment of Myasthenia Gravis. *Proc. R. Soc. M.*, Lond. 1946, 39-600.

G. KEYNES summarized his results in 63 patients subjected to thymectomy for myasthenia gravis. There were 9 postoperative deaths, 7 in the first 21 patients and only 2 in the next 43 patients. Four others had died of the disease. 14 were apparently cured and not taking prostigmine. 15 were very much better taking small doses of prostigmine. 3 showed slight improvement and 9 showed no improvement. In the remaining 9 patients operation had been too recent to permit accurate assessment of the results. The best results were obtained in younger patients with short histories of illness. One factor adversely affecting the results was the incidence of thymic tumors. In the 63 patients there had been 7 tumors. The size of the thymus, apart from

the presence of a tumor, bore no relation to the severity of the disease. Keynes believed that the total results justified continuance of the operation. Technical advances had greatly lowered the mortality in the latter part of his series. Early operation before the disease became chronic, carried a low risk and appeared possibly to prevent thymoma formation.

D. H. COLLINS reported that he and Bratton had studied the glands removed from myasthenic patients and compared them with normal glands taken from healthy individuals who had died suddenly because of accidents. They found that the weight of the normal gland is extremely variable but that its shape and qualitative makeup undergo fairly constant change with increasing age. The majority of the myasthenic glands showed no gross anatomical abnormality but about 1 in 7 showed the presence of a thymic tumor. Tissue elements more specific to the thymus, i.e. reticulated medullary epithelium and the Hassall bodies, did not appear to undergo any constant or significant change in myasthenia gravis except in the case of tumors in which both the lymphoid and epithelial elements were concerned in the new growth. Two features distinguished the nontumor gland of myasthenia gravis from the normal thymus—less marked cortical atrophy than in the normal gland and the intramedullary formation of structures apparently identical with the germ centers or secondary nodules of Flemming commonly seen in lymph glands. Whether these changes were related to the cause or to the effects of the disease could not be determined.

P. MARTIN pointed out that on the basis of Keynes figures, thymectomy was not the complete answer to the problem of myasthenia gravis. In younger patients, in whom the disease has always been more severe, the operation has been a tremendous therapeutic advance, often a lifesaving measure but in older individuals the effects of operation have been less pronounced. He raised the question of whether or not improvement noted only several months after operation should not be attributed to a remission rather than to the operation.

C. SYMONDS suggested a comparison of Keynes series of cases with a number of cases followed through the preprostigmine years and also with more recent cases given prostigmine but not subjected to surgery. He believed that the average expectation of health and life had been much less than that now offered by surgery.

L. P. E. LAURENT stated that in his experience with some 65 cases of myasthenia gravis over a period of 18 years he had seen some very remarkable remissions and had come to believe that the prognosis was much better than had been generally thought. He cited several cases, in 1 of which the patient had had severe symptoms for 7 years but had now gone 30 years without relapse. It was his opinion that any thymic theory of the causation of myasthenic symptoms would have to be reconciled with M. Walker's experiment in which she showed that

release of a cuff around the arm after exercising the muscles of the forearm caused a rapid ptosis.

P. H. SANDRER raised the question of radiotherapy to the thymus in myasthenia gravis, asking Keynes whether he had removed glands previously subjected to radiation and if so, what histological changes he had noted. He stated that several of his patients who had received radiation had benefited markedly while others had been benefited little or not at all.

B. F. LOEWENSTAM, M.D.

Millan Gutierrez, J.: Leishmaniasis of the Skin and Mucosae (Leishmaniasis de la piel y de las mucosas). *Med. rev. mex.* 1946, 26: 150.

Millan Gutierrez gives a very good discussion on leishmaniasis.

The clinical forms of the "Boton de Oriente" described are the abortive, dry and squamous, crustaceous, that found in layers, the cheloid verrucous, and the cutaneous tumors.

The clinical forms are divided in 3 main groups: the ulcerous, nonulcerous, and that with secondary ulcerations.

The phlebotomy is found to be the mosquito which transmits the disease.

The different therapeutic measures against the disease are discussed as well as the preventive measures to avoid its propagation.

WILLIAM E. RICKETTS, M.D.

Begnis G. S., and Picena, J. P.: Fibrosarcoma of Darier Occurring after a Bite Wound (Fibrosarcoma de Darier sobre cicatriz por mordisco). *Rev. med. Reroris* 1946, 36: 235.

Begnis and Picena report the case of a 35 year old man who was bitten in a fight with another man 9 years ago. The wound was inflicted in the anterior part of the thorax above the mammary gland. Four years after the fight he developed a tumor in the scar of the bite, which was extirpated surgically. Later this tumor recurred and upon histological examination was found to be a fibrosarcoma of Darier.

DUCTLESS GLANDS

Fontaine, R., and Pilla, P.: Remarks Concerning 39 Interventions on Thymus and Parathyroid Glands (Réflexions à propos de 39 interventions sur le thymus et les parathyroïdes). *Ann. endocr. Par.* 1946, 7: 7.

The authors performed 45 operations on the thymus and the parathyroid glands. Six operations were performed on patients with polyarticular deforming rheumatism. The remaining 39 procedures are divided into three groups: 4 thymectomies, 12 thymoparathyroidectomies, 20 parathyroidectomies, and 3 so-called physiologic parathyroidectomies or resections of terminal branches of both lower thyroid arteries.

The diagnoses were as follows: chronic ankylosing polyarthritis, 24 cases; scleroderma, 8 cases; nephro-

lithiasis, 2 cases; Lobstein's disease, myositis ossificans, lipoid granulomatosis, progressive myasthenia, and primary amenorrhea, 1 case of each.

In ankylosing polyarthritis, thymoparathyroidectomy proved superior to all other procedures. Bacillary rheumatism responds poorly to operations on endocrine organs; however, better results may be obtained in polyarthritis of endocrine origin. The authors state that a distinction between both forms of rheumatism is not always easy to make. Better results are obtained in spondylitis than in peripheral forms of rheumatism. It is believed that patients with hypercalcemia show a better response to operation than those with a normal calcium level. Of 24 patients with ankylosing chronic polyarthritis, good results were obtained in 11 or 45.8 per cent of the cases.

Parathyroidectomy is a valuable procedure in the treatment of scleroderma if the condition is progressing slowly while forms of the disease having a rapid course with involvement of other endocrine glands respond poorly to the operation.

Operation was unsuccessful in a 6 year old child with Lobstein's disease who continued to sustain fractures after the operation.

A considerable functional amelioration with cessation of pains and further ossifications was obtained by parathyroidectomy in 1 patient with myositis ossificans.

Thymectomy and physiological parathyroidectomy produced relief in a patient with calculi of the urinary bladder. Parathyroidectomy failed to produce good results in a patient with lipoid granulomatosis mistaken for Recklinghausen's disease.

Apparently a favorable effect of thymectomy on myasthenia was noticed in 1 patient.

If a primary amenorrhea does not yield to hormonal therapy a persistent thymus may be responsible for the condition. This hypothesis was confirmed by good results of thymectomy in a 21 year old girl.

JOSEPH K. NARAY, M.D.

Venning, E. H.: Adrenal Function in Pregnancy. *Endocrinology* 1946, 30: 303.

The important contributions made in recent years with regard to the metabolic changes produced by the adrenal cortical steroids show that the various functions of the adrenal gland, such as salt and water metabolism, carbohydrate and protein metabolism, and androgenic activity can be correlated with different groups of steroid hormones. Evidence is accumulating to indicate that these various functions are able to exert their influence independently of one another.

The urinary excretion of glycocholic corticoids, ketosteroids, pregnandiol, estrogens, and gonadotropins has been followed in 9 cases of pregnancy.

The excretion of adrenal metabolites in pregnancy suggests that at least the corticoids, those compounds of adrenal origin which have a specific effect on carbohydrate and protein metabolism, and the 17-ketosteroids can vary independently of one another. The

is seen in Cushing's syndrome in which the urinary corticoids are strikingly increased and the 17-ketosteroids are usually within the normal range. In cases of hirsutism the reverse is found—high 17-ketosteroids with normal corticoid excretion. In children the corticoid excretion has reached the adult level between the ages of 5 and 7 years whereas the 17-ketosteroids do not reach this level until a much later age. In the series of pregnancy cases a marked increase in excretion of corticoids was found with very little change in the 17-ketosteroids.

There is an initial rise in excretion of corticoids in the first trimester of pregnancy which usually returns to normal levels between the 10th and the 12th days. Between the 14th and the 16th days the urinary corticoids increase again and reach relatively high values.

A falling off in excretion usually occurs in the last month and shortly after parturition the values are back to normal again.

The ketosteroids when measured by the Pincus reaction remain at the same level throughout pregnancy. When the same fraction is assayed by the Zimmermann reaction, an increase in ketosteroid excretion is seen beginning between the 14th and the 16th days. This increase in ketosteroids is attributed to the increased excretion of 20-ketosteroids. Only a slight increase is observed in the β -OH (beta hydroxy) ketone fraction.

The high excretions of corticoids observed in pregnancy are surprising as they are in the order of amounts found in the urine of persons after severe damage or of patients suffering with Cushing's syndrome and indicate that the activity of the adrenal gland must be greatly increased at this stage of pregnancy. The well known phenomenon of rapid growth of the fetal adrenal cortex during the last trimester of prenatal life and its subsequent degeneration beginning at or just previous to birth suggest the possibility that the fetal cortex might be contributing to the increased output of corticoids during the latter part of pregnancy. However on examination of the urine obtained from infants in the first 4 days of life little or no corticoid activity can be found. Within 3 to 4 days after delivery the excretion of corticoids in the mother is back to normal values.

Just what the cause and function of this increase in adrenal activity may be is not known.

STEPHEN A. ZIMMAN, M.D.

EXPERIMENTAL SURGERY

Murphy, J. J., Ravdin, R. G., and Zintel, H. A.: The Use of Streptomycin in Experimental Peritonitis. *Surgery* 1946 20: 445.

Streptomycin is an antibiotic which is relatively nontoxic, and which, following parenteral administration, is widely distributed in the body fluids. Its effectiveness against many strains of organisms of the colon group differentiates it strikingly from penicillin. Since the organisms of the colon group are the types most frequently found in the common

forms of human peritonitis, it seemed logical to substitute streptomycin for sulfonamides and penicillin both of which gave favorable results.

In experimentally produced peritonitis streptomycin was found in significant amounts in the peritoneal fluid. Despite the dosage used in the experiments, which is not the maximum dosage which may be safely administered, the survival rate of the streptomycin treated animals was 60 per cent as compared with a survival rate of 30 per cent among the control animals. SAMUEL KAHN, M.D.

Burns, F. J.: Reaction of Tissue to and the Fate of Oxidized Cellulose in the Peritoneal Cavity of the Dog. *Arch. Surg.* 1946 53: 348.

Oxidized cellulose appears to be a hemostatic agent which can be left in the tissues without causing untoward effects. Cellulose which occurs in relatively pure form in cotton can be oxidized by the action of nitrogen dioxide. If the oxidation is sufficiently complete the material becomes completely soluble in dilute solutions of alkali. If the oxidation is insufficient to give the material a carboxyl group content of 13 per cent, the material is only partially soluble.

By implanting bits of oxidized cellulose in various parts of the peritoneal cavity of dogs, the author has shown the ultimate fate of the material and the reaction of the tissues to it. Eight-ply pieces of gauze 2 by 1 cm. in size were placed in each of four locations—in the pelvis in the omental bursa, among loops of intestine, and between the liver and diaphragm. The peritoneal cavities of the animals were reopened at varying intervals until such time as the gauze was absorbed and sections from the omental bursa were taken for microscopic study.

As the gauze was being absorbed it formed a brown gelatinous mass, which became smaller until absorption was complete. This required about 28 days, when the gauze was placed in the omental bursa. In each of the other sites absorption of the gauze was complete in about 2 days. When larger pieces of gauze were placed among loops of intestine the time for absorption was correspondingly longer—10 days for an eight-ply piece 4 by 5 cm., and 13 days for an eight-ply piece 4 by 4 cm. Although absorption time is governed by the amount of gauze present, other factors are concerned in the process. The nature of the tissue, the amount of peritoneal fluid and its type, the mechanical mobility of the tissues surrounding the gauze and the degree of oxidation of the gauze all influence the absorption. In some instances fibrinous adhesions were seen to be present during the process, but in no case did these persist after absorption was complete.

Study of the microscopic sections showed that the tissue juices dissolved the gauze to some extent but that a large part of the absorption was effected by phagocytosis. Early a moderate acute inflammatory reaction was seen, with many neutrophils present. Later large numbers of macrophages were evident, surrounding the gauze fibers and causing

them to disintegrate. Under the attack of the macrophages the fibers became ever smaller until they disappeared completely.

The author suggests the use of oxidized cellulose as a substitute for the hemostatic gauze pack. He suggests that it may be used for hemostasis either by itself or in combination with some blood derivative such as thrombin.

HOSPITALS MEDICAL EDUCATION AND HISTORY

Cobb, W. M.: A Graphic Approach to a Complete Anatomy. *J. Nat. M. Ass. N. Y.* 1946 38: 155.

In 1489 Leonardo da Vinci began work upon an encyclopedic human anatomy. Although it was never finished da Vinci's notes outlining the general plan of the treatise show that it was to have been very comprehensive, consisting of 120 books and including correlated subjects of physiology and comparative anatomy. In reviewing da Vinci's work and his truly remarkable grasp of the fundamentals of anatomy the author stresses the current need for synthesis and simplification in the presentation of that subject.

His approach to this problem has taken three forms. The first was a scheme for organization of the anatomical facts, in which the ovum, the 7-week embryo and the erect adult were used as focal points for associations. The second was the development of a canon of proportions with which students could prepare outlines of the human figure with skeleton from the ventral, lateral, and dorsal aspects, outlines which could be utilized for review of specific anatomic features. The third was the use of these basic outlines of the human figure as a common frame of reference for presentation of detailed anatomy of all

parts and regions. Marginal notes on clinical variations and developmental features were integrated with the particular outline, detailing the subject in which they were appropriate.

In constructing a basic outline from the ventral aspect the height of a head is taken as the fundamental unit of measure. Any convenient dimension may be used as a head height. For laboratory work, the head is arbitrarily scaled to 4 inches. Station and shoulder breadth are given the classical values of $7\frac{1}{2}$ and 8 heads, respectively. A rectangular frame $7\frac{1}{2}$ by 8 heads and subdivided into heads and half-heads is prepared. On this frame 10 constant guide points, such as the suprasternal notch, umbilicus, symphysis pubis, knee joint, are plotted. Since they are fundamental, the locations of the 10 guide points must be memorized. Working from these points the student then develops the human figure and skeleton by adding correlated features through 10 successive stages. In early stages anatomic landmarks are inserted at guide points, first outlines of limb bones are drawn, certain ribs and vertebrae are marked out. Later the surface contours and remaining osseous structures are added. Marginal insertions are restrictive, depicting some features in greater detail and adding collateral facts. The stages of construction of dorsal and lateral outlines are not described by the author but the method is the same as for the ventral outline.

The author reiterates the value of studying anatomy from the cadaver, skeleton, and living subject. Excellent illustrations of anatomic outlines prepared by his students, both in the laboratory and in written examinations, show the soundness of his approach. The student need not have any particular artistic aptitude or training to produce good anatomical drawings.

LIGATION OF THE INFERIOR VENA CAVA IN THROMBOEMBOLISM

Report of 36 Cases

BEN R. THEBAUT M.D. and CHARLES S. WARD M.D. Atlanta, Georgia

MUCH has appeared in the medical literature during the past several years on venous thrombosis and pulmonary embolism. The high incidence of thrombosis in the deep veins of the lower extremities and the dangers attending such a process have been stressed. It is the purpose of this presentation to re-emphasize the importance of this disease to discuss its surgical management once pulmonary infarction has occurred and to report on 36 patients whom we have treated by ligation of the inferior vena cava within the past 3 years. To date no authors have advocated routine ligation of the inferior vena cava in cases of pulmonary embolism from venous thrombosis of the deep veins of the lower limbs, or from a clinically hidden source. It is our belief that this procedure will offer the patient with pulmonary embolism the best prognosis for both immediate and ultimate results.

IMPORTANCE AND SIGNIFICANCE OF THROMBOEMBOLISM

Despite the abundance of material in the literature on the subject of venous thrombosis and pulmonary embolism the importance of the disease is as yet not fully appreciated.

Welch and Faxon in a group of 250 cases at the Massachusetts General Hospital found

that the ratio of fatal embolism to recognizable phlebitis without regard to the type or duration of the disease was 1 to 25 (4 per cent). If these figures were adjusted to show the incidence of fatal embolism in cases of recognizable phlebothrombosis alone the ratio undoubtedly would be much higher. Welch and Faxon found moreover that 1 patient out of 3 (33 1/3 per cent) with phlebitis suffered pulmonary infarction at some stage of the disease.

Barker and others (2) in a statistical study of 1665 cases of postoperative venous thrombosis and pulmonary embolism at the Mayo Clinic have concluded that if nonfatal embolism has occurred the chance that a fatal embolism will follow is slightly less than 1 in 5 (20 per cent) and that the chances of subsequent embolism fatal or nonfatal are about 3 in 10 (30 per cent). They state that if all fatal embolisms preceded by clinically diagnosed sublethal emboli could be prevented the total number of fatal embolisms would be reduced more than one third.

McCartney in a study of 25771 autopsy records found 4070 deaths which he considered to be postoperative mortalities. Among this group thromboembolism was present in 471 instances (11.5 per cent) and death was believed to have been caused by pulmonary embolism in 216 (5.3 per cent).

Death from pulmonary embolism may be due to a large clot which occludes the main

From the Whitehead Department of Surgery, Emory University, Atlanta, Ga.

pulmonary artery or its left and right branches it may also result from asphyxia when large areas of the lungs are infarcted from failure of the right side of the heart in the face of rapidly rising pulmonary arterial pressures proximal to the embolic occlusions, or from peripheral circulatory failure due to an insufficient venous return to the left atrium. Perhaps equally as important are the deaths which result from very small emboli as a result of various autonomic reflexes. DeTakats and Fowler state that they have shown that patients may die from a small embolus which occludes a vessel to an insignificant area of the lung. On the basis of animal experiments they believe that a widespread radiation of autonomic reflexes predominantly vagal occurs during embolism. These produce bronchoconstriction, increased bronchial secretion, inhibition of the heart, depression of blood pressure and other effects through smooth muscle spasm, including intestinal colic.

Pulmonary embolism which does not produce death may result in serious lung complications including necrosis, cavitation, abscess and fibrosis.

Pathological demonstrations have shown that a very high percentage of all pulmonary infarctions, even in patients with heart disease, result from emboli which have their origin in the deep veins of the lower extremities. Allen Linton and Donaldson state that Castleman found this to be true in approximately 95 per cent of cases studied at autopsy.

In the female a rather frequent source of pulmonary emboli is thrombosis in the pelvic veins complicating postpartum or postabortal sepsis or operative procedures upon the pelvic viscera. These thrombi may be bland or septic. In the case of bland thrombosis, propagation into the hypogastric vein with breaking off of a portion of the clot will produce pulmonary infarction. In this instance ligation of the inferior vena cava will completely protect against further pulmonary emboli from this source since it is thought that the ovarian veins will not yield emboli of significant size in bland thrombosis (17). If the thrombi are infected or septic, fragmentation of the clot with discharge of septic emboli may produce not only pulmonary infarction but

pyemia. In this case ligation of the inferior vena cava alone may not suffice since small, bacteria laden emboli may continue to enter the general circulation through the ovarian veins. Simultaneous ligation of these veins is therefore to be recommended.

Nelson, Jones, and Collins found a mortality rate of 100 per cent in 30 cases of pelvic thrombophlebitis not operated upon, but state that in general the literature accredits the disease with a 50 per cent mortality. These authors had ligated the inferior vena cava in 8 cases at the time their paper was published. The ovarian veins were interrupted simultaneously in 3 cases. One death occurred following operation in a moribund patient who was offered her only chance of recovery through surgery. The mortality rate was 12.5 per cent in the cases operated upon or one-eighth as high as in those not operated upon.

Thus in cases of pulmonary infarction with no apparent source for emboli, ligation of the inferior vena cava will protect from two very important sources, namely the veins of the lower extremities and the pelvic veins, except the ovarians.

VARIOUS METHODS OF TREATMENT

We have been discouraged by the results of heparin and dicoumarol therapy in patients in whom pulmonary embolism has occurred. This is true in respect to cases which we have personally observed as well as those reported in the literature.

The majority of reported cases which have been treated with these agents are those patients to whom the drugs were given prophylactically to prevent extension of a pre-existing thrombus, or to prevent clotting in patients believed to be susceptible to intravascular thrombosis. The results of treatment in these cases have been good. Nevertheless, there are still too many patients who develop hemorrhagic complications and too many who discharge emboli to the lungs during and after conclusion of the therapy. Results in patients who were started on treatment following pulmonary infarction have been less encouraging because of the failure of these agents in many instances to prevent subsequent infarctions. We are in agreement

with Ochsner and DeBakey (16) who feel that the use of heparin and dicoumarol in the treatment of pre-existing thrombosis is likely to give the physician a false sense of security. This is particularly true in the treatment of a patient already the victim of pulmonary embolism. However as a prophylactic measure before thrombosis has occurred and in the treatment following ligation of the inferior vena cava these drugs may help to prevent thrombus formation or an extension of the thrombotic process into unaffected vessels. Their value in other conditions associated with intravascular coagulation of blood is acknowledged.

We have also been disappointed in treatment of the disease by proximal venous ligation at levels below the common ilacs. We have personally seen a few patients continue to discharge emboli after ligation was performed bilaterally and have noted many other examples mentioned in the literature. Veal and Hussey reported 9 cases of postligation embolism. In 4 of these the origin of the embolus was a point in the femoral vein proximal to the site of ligation. Allen and co-authors advocate bilateral femoral vein ligation with phlebotomy and aspiration of the thrombus if one is present in the segment of vein to be interrupted. They state however that about 5 per cent of their 464 patients had infarcts following this procedure. Some of these were multiple and a few resulted in fatalities. Loewe reported 1 case of fatal embolus after sequential femoral vein ligation and mentioned 4 other patients who continued to throw pulmonary emboli following ligation. Moses, in a very recent report, stated that 2 of his 35 patients with vena caval or iliac vein interruptions were operated upon because of recurrent emboli following bilateral femoral vein ligations. One of these patients died.

Proximal venous ligation at higher levels is apparently the favored procedure at this time over femoral phlebotomy with aspiration of the thrombus. This is due to a greater realization of the danger in leaving even a small portion of thrombus or an area of roughened intima in the vein proximal to the site of its interruption. Such a nidus may become the source of a new propagating thrombus and

pulmonary emboli. There seems to be little doubt that the higher the level of the venous ligation the smaller the risk of recurrent pulmonary embolism. Homans insists that interruption of the femoral vein should always be carried out proximal to the profunda in order to prevent embolism from a thrombus in this vessel. He further states that ligation of the common femoral vein is not as safe as an interruption at a still higher level. He believes that there is usually no thrombus of importance above the external iliac vein and states that this is an important consideration in common iliac and vena caval interruptions.

Fine and Starr in commenting upon the effectiveness of venous ligation in preventing embolism state that, while emboli do occasionally occur following ligation proximal to the thrombus this phenomenon may be explained in almost every instance on the basis of unilateral ligation or ligation performed at too low a level. For this reason they predict that 'vena caval ligation may come to occupy a significant place in the prophylaxis of embolism.

In the surgical treatment of thromboembolism interruption of the major venous channel from both lower extremities is demanded in the light of present knowledge.

It has been demonstrated pathologically that venous thrombosis in the deep veins of the lower extremities occurs probably more often bilaterally than unilaterally. Fine and Starr state that there is little doubt that in at least half of the patients with the disease both extremities are involved. Hunter and co-workers on the basis of findings in 351 cases published in 1941 found bilateral deep leg vein thrombosis in 110 cases as compared to unilateral involvement in 75 cases. Treatment by proximal venous ligation at any level below the inferior vena cava requires operation bilaterally in order to intercept emboli from both lower limbs. However in vena caval interruption a single operation offers protection not only from emboli arising in the veins of both lower extremities but from a pelvic source as well. Although ligation of the vena cava is a procedure of greater magnitude than femoral vein ligation we feel that it is often of lesser magnitude than a unilateral iliac vein

ligation. The one major advantage of femoral vein ligations is the fact that local anesthesia may be used satisfactorily whereas a spinal or general anesthetic is necessary for interruptions of the iliac veins or vena cava. However the added protection of vena caval ligation against further pulmonary embolism makes it the favored procedure except in very exceptional cases. Moses has entirely abandoned the iliac approach during the past year in favor of ligation of the vena cava. He states that vena caval interruption is comparable to ligation of either iliac vein requiring no more anesthesia exposure technical skill or time indeed it requires less of each of these factors than does ligation of the left iliac vein which is short and lies under the aorta.

COLLATERAL CIRCULATION

Second in importance to saving the life of the patient with pulmonary embolism is the consideration of circulatory disturbances in the lower extremities following interruption of their major channels of venous return. Homans has demonstrated anatomically that the collateral circulation following interruption of the common femoral or external iliac vein is far less satisfactory than that following ligation of the common iliac. His own clinical observations and published reports by others are almost uniformly in accord with these anatomic considerations *viz.* edema of the extremity is less severe and of shorter duration following common iliac vein ligation than after interruption of the external iliac or common femoral veins. Moses feels that whenever edema has followed ligation of the vena cava or iliac veins there has been unequivocal evidence of either persistence or recurrence of the disease process. It has been pointed out by Homans and more recently emphasized by O Neil that in collateral venous circulation there is no significant choice between placing the ligature about the two common iliac veins or a few centimeters higher about the inferior vena cava.

O Neil and Weinstein divide the available collateral pathways into three groups which they call the superficial the deep and those of the ascending lumbar trunks. The superficial

group is composed of the superficial circumflex iliac and superficial epigastric veins which connect the saphenous with the superficial thoracic veins and those of the upper abdominal wall. The deep group is made up of the deep circumflex iliac superior epigastric and lumbar veins which connect the external iliac with the internal mammary and ascending lumbar veins. The ascending lumbar trunks beginning on either side of the sacral promontory communicate with the sacral, common iliac hypogastric and ilio-lumbar veins, and at higher levels with the lumbar veins the inferior vena cava and right renal vein. The right and left lumbar trunks become the azygos and hemiazygos veins respectively and ultimately the veins of the azygos system drain into the superior vena cava.

Northway and Buxton (14) have demonstrated the more important collateral channels which function following vena caval obstruction. This was done by means of roentgen studies and dissection following injections of red lead into the femoral veins of cadavers in which the vena cava had been occluded just above the bifurcation. They found that the superior vena cava filled rapidly by way of the ascending lumbar, the segmental veins which associate directly with the vertebral plexuses through the spinal veins, and above the diaphragm by the azygos system which receives the segmental veins and terminates in the superior vena cava. Important communications between the inferior vena cava and the vertebral systems of veins were found. In all cases there was rapid filling of the inferior vena cava above the obstructed point at the bifurcation. The large internal vertebral plexus on the surface of the dura was well filled with the injected material at the time of laminectomy.

In the light of these findings it was feared that an increased blood flow through the para-vertebral venous plexus following ligation of the inferior vena cava might lead to varices in this system with neurological symptoms and signs. However there have as yet been no cases reported to indicate that this has occurred. Furthermore Northway and Buxton (14) reported no abnormal findings following

Fig. Incisions commonly used in ligation of the inferior vena cava: a, right paramedian, for transperitoneal approach; b, c, and d, incisions for extraperitoneal approach.

THE OPERATION

Ligation of the inferior vena cava is not a difficult operation for those experienced in abdominal and vascular surgery. The primary objective is completely and promptly to interrupt the blood flow from the more distal parts through the vena cava so that emboli arising in these distal veins may not by pass the point of ligation.

The site of election for ligation is at the level of the aortic bifurcation. This point is immediately above the junction of the left and right common iliac veins to form the inferior vena cava. It is easily found by palpation through the use of the pulsations of the aorta and of the left and right common iliac arteries.

The approach to the inferior vena cava may be either transperitoneal or extraperitoneal. The transperitoneal approach is preferred in cases in which simultaneous ligation of the ovarian veins is indicated, as in pelvic vein thrombophlebitis with pulmonary infarction or pyemia, or in which simultaneous bilateral interruption of the lumbar sympathetic chain seems advisable. Otherwise the extraperitoneal approach is the method of choice. The extraperitoneal procedure is less shocking to the patient and more easily and quickly executed in the majority of patients, and post-operative complications are less frequent than with the transperitoneal approach. Interrup-

tion of the right lumbar sympathetic chain may be easily accomplished if desired, when this approach is used.

Technique. In the transperitoneal approach, a 5 to 6 inch right paramedian incision is preferred (Fig 1a and Fig 3). It is made with its midpoint at the umbilicus. The operator in his early experience is usually inclined to make the incision too low unless this landmark is kept in mind. When the peritoneal cavity is entered it is helpful to place the patient in a deep Trendelenburg position. The small bowel is displaced into the upper abdomen and the posterior parietal peritoneum overlying the origin of the inferior vena cava is identified and opened parallel to the course of the vessel for about 2.5 inches. The vena cava is freed from its surrounding connective tissue by careful blunt dissection. Care is taken not to injure tributary lumbar segmental veins which enter the vena cava at its posterolateral aspect on either side. An ordinary blunt nosed gall bladder clamp serves admirably for the dissection around the lateral and posterior aspects of the vessel. Two umbilical tape ligatures, placed about 1 centimeter apart, are then passed beneath the vena cava, and the vessel is doubly ligated in continuity.

When there is doubt as to the presence of a thrombus within the vena cava at the point of ligation, this vein may be opened between the two umbilical tape ligatures before they are tied—provided it is clear that no tributaries enter this segment of the vena cava, or if they do that they are ligated prior to incising the vessel. Traction is maintained on these ligatures to prevent bleeding from below and aspiration of air from above. If a thrombus is found the patient is placed in a reverse Trendelenburg position and upon releasing tension on the proximal umbilical tape ligature, suction by means of a glass drinking tube is applied and the clot aspirated. The proximal ligature is then immediately tied. The tension is released momentarily from the distal umbilical tape ligature and the distal portion of the thrombus or as much of it as possible is removed by aspiration. This ligature is then likewise tied securely. Transfixion ligatures of braided silk may be placed between the umbilical tape ligatures as security against the

Fig. 4. Case 24, showing the scar of transverse incision used in an extraperitoneal approach to the vena cava. Photograph showing slight ankle edema as taken 4 months after operation. Six weeks later the edema had cleared completely.

Fig. 5. Case 30. Note the semilunar incisional scar. This patient had left femorofemoral thrombophlebitis, edema, and right deep calf vein thrombosis at the time of pulmonary embolism. Note complete absence of edema 4 months after ligation of the inferior vena cava.

parallel to the natural skin creases leaves a more pleasing scar. It is made at or slightly above the level of the umbilicus from a point just medial to the lateral edge of the rectus muscle to the midaxillary line (Fig. 2). The incision is extended down to the external oblique. The aponeurosis is incised at the border of the rectus muscle and the incision is extended about an inch laterally at which point as a rule the muscle fibers can be split further outward and slightly upward to give adequate exposure of the internal oblique muscle (Fig. 2B). The internal oblique and transversus abdominis muscles are then split

parallel to the course of their fibers, and the peritoneum is exposed. Should the 10th and 11th intercostal nerves be encountered, they are retracted to avoid injury. The peritoneum is bluntly dissected posteriorly and medially until the vena cava is exposed.

The ureter is identified as the dissection proceeds and is retracted medially being dissected up with the peritoneum (Fig. 2C). The psoas muscle, the genitofemoral nerve, and the right lumbar sympathetic chain are seen during the course of the dissection.

The point at which the aorta bifurcates is identified by palpation and at this level the

inferior vena cava is bluntly dissected from surrounding connective tissues, and ligated as described in discussion of the transperitoneal approach.

If indicated, the right lumbar sympathetic chain (Fig 2C) can be interrupted at this time.

When retractors and packs are removed from the wound, the peritoneum falls back and resumes its normal position, and the split transversus and internal oblique muscles come together to leave very little defect in the abdominal wall.

The incision is closed in layers using non absorbable sutures, preferably black silk.

Postoperative care. As with any postoperative patient, treatment following vena caval ligation varies with the problem of the individual. In general postoperative care is given as for any abdominal surgery.

The pulmonary status of the patient may require oxygen, penicillin or other special attention if there is a considerable area of lung infarcted.

Otherwise, we have found the following measures to be helpful in the postoperative care of these patients:

1. Elastic bandages applied snugly to both lower limbs. These should extend from the base of the toes to the groins with only the tips of the heels exposed, until the active process in the deep veins subsides. Later the elastic bandages need extend only as high as the tibial tuberosities. They should be worn continuously while the legs are dependent until the patient is ambulatory without edema. In patients who have extensive involvement of the veins of the lower limbs, support may be necessary for from 6 to 12 months. In others with little involvement except in some of the deep calf veins the use of support for only a few weeks may suffice. Nevertheless elastic bandage support should be maintained until removal without them reveals no detectable edema following dependency for from 1 to 10 hours.

2. Elevation of the foot of the patient 8 to 12 inch elevation of the foot of the patient is required immediately after operation aids in returning venous blood via the collateral system of veins from the lower extremities. By speeding up the return flow of blood this measure may be of value in keeping down ex-

tension of the thrombotic process beyond segments of veins already involved. It is helpful in preventing early postoperative edema.

3. Paravertebral lumbar sympathetic blocks with novocain solution. This procedure is of definite benefit if signs of phlebitis or flex vasospasm develop postoperatively. It is performed unilaterally or bilaterally as indicated and is repeated daily until all evidence of vasospasm disappears.

4. Prostigmin 1:2000 solution. We have used this drug in doses of 1 cubic centimeter subcutaneously every 3 hours to prevent abdominal distention, to aid voluntary urination and to help prevent further intravascular clotting of blood (4).

5. Heparin and dicoumarol. These drugs may be used postoperatively preferably in combination as prophylaxis against propagation of thrombi in the veins of the lower limbs or in the branches of the pulmonary artery. In this series we have used them in only 1 patient (Case 34) who had recurrence of pleuritic pain 48 hours after operation.

(We have consistently noticed that all patients in our series who had severe pleuritic pain for varying periods of time prior to ligation of the vena cava were completely relieved of this pain upon reacting from the anesthetic. This fact has led one of us (B.R.T.) to feel that perhaps the pleuritic pain produced by a single pulmonary embolus is of rather brief duration possibly 1 to 6 hours, and that many patients in whom the pain persists for longer periods are actually having repeated pulmonary embolizations. Two patients in this series had postoperative recurrence of pleuritic pain. In these cases the pain was probably due to peripheral propagation of thrombi from points of previous embolic occlusions of branches of the pulmonary artery.)

6. Ambulation. The patient is encouraged to become ambulatory as soon as possible after operation. The length of time depends upon the degree of pulmonary damage and clearing of the infarcted areas upon the status of the phlebitis and/or edema of the lower extremities and upon the general condition of the patient. In the absence of infection and the presence of a positive protein balance the operative wound is not considered as a factor

M 16 A 120	41	Male	Right deep calf	7-14-46	Extraperitoneal	Slight	None	Increased Right					Patient confined having clinical and x-ray backing of recurrence of original embolism after operation. Treated with heparin and aspirin.
M 17 A 121	41	Male	Right	8-7-46	Extraperitoneal	No	None	None	None				
M 18 A 122	41	Male	Right	8-6-46	Extraperitoneal	No	None	None	None				Patient probably had recurrent pulmonary embolism. No autopsy. Primary cause for embolism apparently arising from bilateral deep calf vein thrombosis.

in determining when to permit the patient to leave his bed

PRESENTATION AND DISCUSSION OF CASES

Of the 36 cases reported, 34 were treated for pulmonary embolism by ligation of the inferior vena cava. The pertinent data on these patients are recorded in Table I. The other 2 died on the operating table before the vena cava was ligated.

One incisional hernia and 2 intestinal obstructions, 1 complete and 1 incomplete developed postoperatively. In these 3 cases the transperitoneal approach was used. Other postoperative complications consisted of 1 wound infection and 1 case of pharyngitis and titis media.

No attempt has been made to differentiate between thrombophlebitis and phlebothrombosis, since the purpose of the paper is to treat only the matter of procedure once pulmonary embolism occurs from the legs or pelvis regardless of the primary disease. All of the patients had had at least one episode of pulmonary embolism and some more than one. Prophylactic ligation before embolism was not done in any case.

Seventeen of the patients were colored and 19 were white. Seventeen were females and 19 were males. The age incidence showed the majority to be between 21 and 40 years of age. It is noteworthy that 3 of these patients were between 10 and 20 years of age, 10 between 21 and 30 and 5 above 50 years of age.

In this small series little correlation between the clinical location of the thrombosis and the occurrence of pulmonary embolism was apparent. Eight patients were afflicted with bilateral femorohiatic disease, 6 with bilateral deep calf vein thrombosis, 3 with femorohiatic on one side and deep calf vein thrombosis on the other, 5 with femorohiatic disease on one side and no clinical evidence of disease on the other, 5 with only unilateral deep calf vein thrombosis and 9 patients showed no clinical findings suggestive of disease in either lower extremity.

Results have been classified under two general headings: immediate effects and late effects. Immediate effects should be taken to mean the changes occurring within 10 days

after the operation. Within this period, 14 showed no effect on the thrombophlebitis; neither pain, temperature, nor tenderness was increased. Eighteen showed definite aggravation of the disease. Immediately after operation the edema increased in 20 but 12 showed no increase. These findings are especially interesting in view of the fact that vena caval ligation has been performed therapeutically for chronic thrombophlebitis with edema.

All patients were seen for later follow up studies. The length of time elapsing between operation and last observation varied between 33 months and 2 months. Late effects on some of the living patients have not been recorded since the time lapse has been too short. Twenty-six patients have no pain. One patient has occasional cramping pains in the calves of the legs. Twenty-seven patients have no varicosities. No edema is apparent in 19 patients (Figs 3 and 5). 6 patients have slight dependent edema after standing all day and 2 patients have slight persistent edema. In none is the edema incapacitating. It is doubtful whether the edema in this series of cases is any greater than would have been anticipated had not vena caval ligation been performed.

Lumbar sympathectomies were done at the time of vena caval ligation on 7 of the cases. Four of these operations were performed bilaterally and 3 were confined to the right side. In 6 of these cases the disease intensified clinically as evidenced by an increase in pain or tenderness or there was an increase in edema. It is interesting to note that in Case 34, with bilateral deep calf vein thrombosis there was a transient increase in calf pain on the side upon which the lumbar sympathectomy chain was interrupted.

Four patients died. Of these Patient 5 died 5 hours after the operation. Autopsy revealed an acute cor pulmonale and multiple bilateral pulmonary infarcts. Patients 29 and 36 died on the operating table before vena caval ligation was effected. Patient 29 was a cardiac in mild failure at the time of operation and both patients had had several episodes of pulmonary embolism. Autopsies were not obtained on these 2 cases. Patient 32 died 20 minutes after closure of the incision. Autopsy

revealed a large embolus completely occluding the left pulmonary artery. Apparently these patients do not tolerate surgery well if operation is delayed until after massive pulmonary infarction has occurred. Vena caval ligation is advocated as soon as possible therefore, after the first embolism has occurred. Case summaries with brief comments on the patients who died are given below.

Forty-eight hours after operation Patient 34 experienced increased chest pain. Patient 26 had a similar episode of pain 48 hours postoperatively. She recovered completely without specific therapy. It was assumed that there had been an extension of an embolus lodged in a branch of the pulmonary artery prior to operation in both of these cases. In Case 34 it is interesting to note that although the patient was placed on heparin and dicumarol at the time of recurrence of the pain 7 days later he again suffered from an acute exacerbation of pain in spite of a decrease in prothrombin to a level ranging between 15 and 30 per cent of normal. This gradually subsided and since that time he has had no further chest pain. X-ray studies confirmed the impression that no new areas of pulmonary infarction were present. None of the patients showed evidence of any new pulmonary embolism after vena caval ligation.

Since many writers are advocating bilateral ligation of the femoral veins above the site of thrombosis as treatment of pulmonary embolism, Patient 31 merits special note. Both femoral veins were simultaneously ligated after pulmonary embolism had developed with evidence of bilateral deep calf vein thrombosis. Subsequently the patient suffered a new embolus. The vena cava was ligated and the patient made an uneventful recovery. During the past year the writers have had 2 patients (unreported) die from fatal emboli subsequent to bilateral femoral vein ligations for deep calf vein thrombosis with pulmonary embolism.

SUMMARIES OF FATAL CASES

CASE 5 J. C., Hospital No. 262966 a 35 year old colored male was admitted to the Medical Service of Grady Memorial Hospital on March 29, 1945 for severe congestive heart failure. One year previously he had developed cardiac decompensation and treat-

ment was given in the out-patient department. Despite treatment he became severely decompensated in March, 1945. Response to bed rest, diuretics, and the removal of 900 cubic centimeters of clear amber fluid from the right pleural cavity in addition to digitalis was good. The patient's weight dropped from 177 to 155 pounds by the 5th hospital day. On April 4, 1945 the 7th hospital day, he suddenly developed severe pain in the lower right anterior chest. This pain was inadequately relieved by intramuscular nerve block with novocain solution. An x-ray film of the chest on the following day revealed a density in the right cardiophrenic angle consistent with a pulmonary infarction. The lower extremities were negative for any signs suggesting phlebitis until April 8, 1945 the 11th hospital day when both calves became tender to pressure and Homans' sign became positive bilaterally. Femoral vein tenderness was also noted at this time. By this time the patient's general condition had gone rapidly downhill from repeated episodes of pulmonary embolism. Since it was obvious that death was certain unless the emboli were interrupted, the patient was prepared and with the use of spinal anesthesia (15 cc. of pontocaine) the inferior vena cava was ligated following a transperitoneal approach. The patient stood the procedure well, but 5 hours after completion of the operation he died suddenly. An autopsy was performed, and pathologic studies revealed multiple bilateral pulmonary infarctions, acute or palmonale fectic aortitis and valvulitis with aortic insufficiency. It is believed that the patient's death resulted from acute failure of the right side of the heart due to massive embolic obstructions of the pulmonary arterial tree.

Several mistakes in the management of this patient are now obvious. No treatment, except symptomatic, was given for pulmonary embolism until 4 days after its onset and vena cava ligation was carried out transperitoneally in a patient critically ill. It is interesting to note that this cardiac patient had no signs of venous disease in the lower limbs until almost dead of pulmonary infarctions and that when signs developed in the calves, the femoral veins were noted to be tender as high as the inguinal ligaments, indicating that thrombi had already propagated to the external iliac veins.

Should we face the same problem today we would ligate the inferior vena cava extraperitoneally as soon as the diagnosis of pulmonary infarction had been made, irrespective of an absence of signs of venous disease in the lower limbs and regardless of the comparatively small possibility of the heart itself serving as a source for the pulmonary emboli. If,

following ligation, there should be recurrence of pleuritic chest pain in the same or in a different location heparin and dicoumarol would be started immediately. It is possible that this patient would be living today had this plan of treatment been followed.

CASE 29. G. McC. Hospital No 56427 a 45 year old colored female was first seen in the surgical outpatient clinic, Grady Memorial Hospital, on June 6 1946. She complained of pain and swelling in the left upper thigh. Examination revealed edema and tenderness in the region of the femoral vessels in the upper left thigh. There were no signs of phlebotrombosis in either leg. A diagnosis of cellulitis was made by the examining intern. Bed rest at home and sulfadiazine were prescribed. The patient returned on June 20 1946 and was admitted to the hospital on the surgical service. She stated that on the previous night she experienced a sudden severe pleuritic pain in the right chest which persisted. On the morning of admission she developed hemoptysis. Examination revealed an acutely ill patient who was dyspneic and coughing up large amounts of bright red blood. Temperature was 98.6 pulse 120 respiration 40 blood pressure 180/120. The heart was moderately enlarged to the left. Physical signs of consolidation of the lower lobe of the right lung with friction rub were present. A ray examination of the right chest suggested pulmonary infarction of both lower lobes. There was a plus pitting edema of both legs and feet, and tenderness along the course of the left femoral vein was noted. There was no calf tenderness, and Homans sign was negative bilaterally. Upon the recommendations of the medical consultant, rapid digitalization with lanatoside C was started 2 hours after admission to the ward and a mercurial diuretic was given intravenously. One hour later the patient was transported to the operating room for ligation of the inferior vena cava. Within 5 minutes after beginning the administration of nitrous oxide and oxygen to induce anesthesia the patient had a sudden respiratory arrest which could not be overcome. Autopsy permit was refused.

The cause of death in this patient was probably a massive pulmonary embolus which occurred during induction of the anesthesia. Since respirations ceased so abruptly and preceded cardiac standstill by a few moments. However, we cannot definitely rule out anoxia as playing an important rôle in view of the large area of pulmonary tissue already limited by previous infarctions plus the limited amount of oxygen permitted with nitrous oxide induction.

Obviously this patient needed emergency treatment in an effort to save her life. She had been throwing emboli for less than 24 hours at

the time of her death and this fact, plus the physical and x ray findings upon admission to the hospital, suggested that large emboli were being discharged probably from a left femoroiliac venous thrombosis. Femoral ligations therefore were felt to be out of the question. Iliac or vena caval ligation seemed indicated. Since local anesthesia is unsatisfactory for either of these procedures, a general or a spinal anesthetic was necessary. Because of the marked hypertension a general anesthetic was preferred.

It seems that inhalation anesthetic agents with which adequate oxygen is given will prove to be the safer for vena caval ligation especially in patients with extensive pulmonary infarction.

CASE 32. W. R. Hospital No 214204 a 45 year old colored male was admitted to the medical service of Grady Memorial Hospital on July 9, 1946. Three weeks previously the patient had developed superficial ulcerations on both shins accompanied by edema of the legs, feet and ankles. The ulcers had healed and the swelling had almost completely subsided. The history did not suggest the cause of the ulcerations but since the patient was totally blind it was believed that they were traumatic in origin. The patient was otherwise well until a day prior to admission when he developed a dull aching pain in the lower left anterior chest which soon came to resemble pleurisy. The onset of pain was accompanied by a cough which was productive of mucoid sputum. Both symptoms persisted. On the day of admission he began coughing up bright red blood. Physical examination revealed temperature to be 102.6 pulse 120, respiration 42 blood pressure 105/70. The patient was orthopneic and appeared acutely ill. There were signs of lung consolidation in the left lower lobe posteriorly and some evidence of free fluid in the left pleural space. Thoracentesis yielded 50 cubic centimeters of old and fresh serosanguinous material. The lower extremities revealed a plus pitting edema of the legs and feet. The left calf was slightly larger than the right. There was no tenderness along the course of the femoral or popliteal veins nor tenderness to compression of the calf muscles. Homans sign was negative bilaterally. An x ray study of the chest showed a pleural effusion on the left with shift of the mediastinum to the right. For reasons unknown, the patient received no treatment whatever until 12 hours after admission to the hospital when a preoperative hypodermic was administered. Shortly thereafter he was taken to the operating room. Under spinal anesthesia supplemented with local infiltration of 1 per cent novocain and sodium pentothal intravenously the inferior vena cava was ligated through a right lumbar incision by an extraperitoneal approach. The

patient went into shock as the muscle layers of the abdominal wall were split for exposure of the peritoneum. In spite of blood plasma and other measures to combat the circulatory collapse he failed to respond and died a few minutes after conclusion of the operation.

It was the clinical impression at the time that the patient's circulatory collapse resulted from a large pulmonary embolus which was thrown off prior to interruption of the inferior vena cava.

Autopsy revealed a large embolus completely occluding the left main branch of the pulmonary artery and massive infarction of the lower lobe of the left lung. Small adherent thrombi were found in the prostatic plexus of veins. No premortem clots were demonstrated in the iliac veins. Permission for exploration of the large veins below the inguinal ligaments was not granted.

Had operation been carried out promptly upon admission to the hospital it is possible that this patient would have survived since his death was apparently the result of recurrent pulmonary embolism. Although the source of the emboli was not demonstrated at autopsy it is probable that they arose from thrombi in one or both femoral veins.

CASE 36 J. J. Hospital No. 161-625 a 71 year old white male was first seen in February 1946, complaining of dyspnea and retrosternal fullness of sudden onset. Examination revealed a blood pressure of 130/80. The heart was slightly enlarged and there was a harsh systolic murmur at the apex. Numerous moist rales were heard in the lower lobe of the right lung. There was a slight edema of both feet. The dyspnea disappeared following an intravenous injection of a mercurial diuretic. X-ray examination of the chest 4 days later revealed a small pleural effusion on the left and a small area suggestive of infarction in the left lower lobe.

His condition remained satisfactory until April 8, 1946 when there was an acute recurrence of dyspnea. Examination revealed moist rales at the left lung base distention of the neck veins and cardiac fibrillation. He responded as before to the same treatment. Four days later the dyspnea recurred, and he developed a cough productive of mucopurulent sputum. He continued to have dyspnea intermittently. The lower extremities remained conspicuously negative for signs of phlebitis.

On June 15 1946 the patient developed hemoptysis. X-ray examination of the chest showed a partial atelectasis of the right upper and lower lobes. It was the clinical impression at that time that the patient had a bronchogenic carcinoma. He was hospitalized for roentgen therapy. There was roentgenological evidence of improvement of the stlectatic process after several weeks.

On August 8 1946 he developed areas in the left lung suggestive of pulmonary infarctions. A surgical

consultation was requested at this time. In view of the x-ray evidence of pulmonary infarctions, it was decided to ligate his inferior vena cava although his lower extremities remained negative.

He received 0.75 gram of sodium pentothal intravenously as an induction agent. Following this he was given nitrous oxide, oxygen, and ether. A transverse skin incision was made and the external oblique muscle was divided. At this point, respiration and pulse stopped suddenly and the patient failed to respond to stimulants and artificial respiration. Permission to perform an autopsy was not obtained.

The cause of death in the patient remains unexplained. It is possible that he had a massive pulmonary embolus on the operating table. On the other hand, he had been sick for 6 months and was a poor surgical risk. This case serves to emphasize the suggestion that if the vena cava is to be ligated, it should be done as soon as possible after the first embolus is recognized.

In retrospect the question has arisen as to whether or not this death was due to a poor choice of anesthetic agents. It is felt that sodium pentothal is not the safest anesthetic for elderly or poor risk patients.

SUMMARY AND CONCLUSIONS

- 1 The importance and significance of thromboembolism and the various methods of treatment are discussed.
- 2 The advantages of ligation of the inferior vena cava are presented.
- 3 The operative technique of vena caval ligation is described in detail.
- 4 Thirty-six cases of thromboembolism are reported. In 34 patients ligation of the inferior vena cava was performed. Two patients died on the operating table before ligation could be accomplished. There was no known recurrence of pulmonary embolism in any of the patients operated upon.
- 5 Follow up studies are presented.
- 6 Ligation of the inferior vena cava is recommended as the treatment of choice in patients with thromboembolism.

TOTAL GASTRECTOMY

Report of 89 Cases

FRANCES H SMITH M.D., Boston, Massachusetts

SINCE the first report of a total gastrectomy in 1884 more than 300 have been reported in the literature. In 1943 Pack and McNeer collected all of the published reports, of which there were 283 operations, and added 20 of their own. In this study the outstanding facts were the high operative mortality and the few instances of long survival. That these should be the outstanding features was to be expected from the nature of the lesions for which this procedure is required and the relative inexperience with which surgeons of necessity operated.

In 1927 the first total gastrectomy was performed at the Lahey Clinic and 88 additional operations had been done by October 1, 1945. Since there have been few reports (2-3) of a large number of cases from any one clinic, the information gained from these 89 operations seems worthy of presentation.

CRITERIA FOR SELECTION OF CASES

The history of the patient was more or less nonspecific and offered little assistance in determining the need for total gastrectomy. In every case, however, there was roentgenologic evidence of a lesion involving the stomach. In many the lesion was extensive in others although localized the cardia or the lower end of the esophagus or both were known to be involved preoperatively. A fixed lesion or involvement of additional sites in the small intestine or colon demonstrable by roentgenologic examination, a mass palpable in the epigastrium, palpable nodules in the liver, a supraclavicular node, or a rectal shelf were considered to be contraindications to exploration (1).

In some instances the necessity for total gastrectomy was not realized until the stomach was examined at the time of operation. Careful exploration under the direct vision of

an abdominal approach provided the most satisfactory determination of the extent of the lesion, the presence of local or distant abdominal metastases and consequently the advisability of attempting the operation. The paper by Lahey and Marshall gives detailed indications for total gastrectomy.

AGE AND SEX DISTRIBUTION

In this series there were 51 male patients and 38 female patients. The youngest was 23 years of age and the oldest 75. The age distribution is shown in Table I. There were 2 patients in the third decade and 11 who were 70 years of age or over, of whom 3 were 75. In this latter group 5 patients survived the operation, 1 of whom lived for 2 years and 1 is still alive 18 months after operation. Although the largest number of patients fell within the age range of 40 to 70 years, it is important to remember not only that patients less than 40 years of age (10 per cent in this series) may develop lesions necessitating total gastrectomy but also that an age of 70 or greater is not a contraindication to this extensive procedure.

SYMPTOMATOLOGY

The duration of symptoms from the time of their onset until the patient was first seen at the Clinic is shown in Table II. In more than half of the patients this was 6 months or less and in one-fourth it was 3 months or less. This should serve to emphasize the necessity for prompt and thorough investigation of any patient with gastrointestinal complaints and to condemn the far too prevalent practice of symptomatic treatment until the patient develops unmistakable evidence of disease.

The most common presenting symptoms in these patients are listed in Table III. Examination of this table shows that there is no suggestive symptom or syndrome. Unexplained loss of weight in patients with digestive com-

plants suggests a malignant lesion in the gastrointestinal tract. Loss of weight occurred in 66 patients of this series (Table IV). In 28 the loss was more than 20 pounds. Twenty two had gastric fullness and pressure, 8 had an ulcer syndrome, 8 diarrhea, 6 dysphagia, indigestion, and heartburn. All of these symptoms indicated disturbance in gastrointestinal function but none could be considered specific for a gastric lesion. These self-evident facts are mentioned to stress the point that although a careful history may in some instances lead to a correct diagnosis in many the complaints are so nonspecific and even apparently unimportant that the diagnosis may be missed or delayed until too late for successful surgical intervention unless the insidious symptomatology is constantly borne in mind.

CLASSIFICATION OF LESIONS

There were 88 malignant tumors, 2 benign tumors which were leiomyomas, and 3 non-neoplastic lesions, of which 2 were chronic gastritis and 1 showed multiple ulcers. The malignant tumors consisted of 81 carcinomas of which 48 were carcinoma simplex and 25 adenocarcinoma. 4 sarcomas of which 3 were lymphosarcomas and 1 a leiomyosarcoma, and 3 lymphomas. Of the latter 2 were classified as Hodgkin's disease and 1 as malignant lymphoma. The pathologic classification of all the lesions is given in Table V.

As has been pointed out by Lahey and Marshall carcinoma of the stomach may be readily divided into two types one the localized type which rapidly metastasizes to adjacent lymph nodes and the other the linitis plastica or leather bottle type in which the carcinomatous infiltration spreads through the muscle bundles in the gastric wall and makes a rigid but comparatively rarely metastasizing lesion which is appropriate for total gastrectomy.

The infiltrative and slowly metastasizing properties of lymphosarcoma also make the patient with this malignant growth a good risk for total gastrectomy. Patients with low grade malignant and benign lesions causing esophageal obstruction at the cardia also have yielded good results with this operation.

PREOPERATIVE BLOOD STUDIES

Much has been written about the effect of malignant disease of the stomach on the blood.

TOTAL GASTRECTOMY

Report of 89 Cases

FRANCES H. SMITH M.D., Boston, Massachusetts

SINCE the first report of a total gastrectomy in 1884 more than 300 have been reported in the literature. In 1943 Pack and McNeer collected all of the published reports of which there were 283 operations, and added 20 of their own. In this study the outstanding facts were the high operative mortality and the few instances of long survival. That these should be the outstanding features was to be expected from the nature of the lesions for which this procedure is required and the relative inexperience with which surgeons of necessity operated.

In 1927 the first total gastrectomy was performed at the Lahey Clinic and 88 additional operations had been done by October 1, 1945. Since there have been few reports (2-3) of a large number of cases from any one clinic, the information gained from these 89 operations seems worthy of presentation.

CRITERIA FOR SELECTION OF CASES

The history of the patient was more or less nonspecific and offered little assistance in determining the need for total gastrectomy. In every case, however, there was roentgenologic evidence of a lesion involving the stomach. In many the lesion was extensive; in others, although localized, the cardia or the lower end of the esophagus or both were known to be involved preoperatively. A fixed lesion or involvement of additional sites in the small intestine or colon demonstrable by roentgenologic examination, a mass palpable in the epigastrium, palpable nodules in the liver, a supraclavicular node, or a rectal shelf were considered to be contraindications to exploration (1).

In some instances, the necessity for total gastrectomy was not realized until the stomach was examined at the time of operation. Careful exploration under the direct vision of

an abdominal approach provided the most satisfactory determination of the extent of the lesion, the presence of local or distant abdominal metastases and, consequently, the advisability of attempting the operation. The paper by Lahey and Marshall gives detailed indications for total gastrectomy.

AGE AND SEX DISTRIBUTION

In this series there were 51 male patients and 38 female patients. The youngest was 21 years of age and the oldest 75. The age distribution is shown in Table I. There were 2 patients in the third decade and 11 who were 70 years of age or over, of whom 3 were 75. In this latter group 5 patients survived the operation, 1 of whom lived for 2 years and 1 is still alive 18 months after operation. Although the largest number of patients fell within the age range of 40 to 70 years, it is important to remember not only that patients less than 40 years of age (10 per cent in this series) may develop lesions necessitating total gastrectomy but also that an age of 70 or greater is not a contraindication to this extensive procedure.

SYMPTOMATOLOGY

The duration of symptoms from the time of their onset until the patient was first seen at the Clinic is shown in Table II. In more than half of the patients this was 6 months or less and in one-fourth it was 3 months or less. This should serve to emphasize the necessity for prompt and thorough investigation of any patient with gastrointestinal complaints and to condemn the far too prevalent practice of symptomatic treatment until the patient develops unmistakable evidence of disease.

The most common presenting symptoms in these patients are listed in Table III. Examination of this table shows that there is no suggestive symptom or syndrome. Unexplained loss of weight in patients with digestive com-

plants suggests a malignant lesion in the gastrointestinal tract. Loss of weight occurred in 66 patients of this series (Table IV). In 28 the loss was more than 20 pounds. Twenty-two had gastric fullness and pressure. 8 had an ulcer syndrome. 8 diarrhea. 6 dysphagia, indigestion and heartburn. All of these symptoms indicated disturbance in gastrointestinal function but none could be considered specific for a gastric lesion. These self-evident facts are mentioned to stress the point that although a careful history may in some instances lead to a correct diagnosis in many the complaints are so nonspecific and even apparently unimportant that the diagnosis may be missed or delayed until too late for successful surgical intervention unless the insidious symptomatology is constantly borne in mind.

CLASSIFICATION OF LESIONS

There were 88 malignant tumors, 2 benign tumors which were leiomyomas, and 3 non-neoplastic lesions of which 2 were chronic gastritis and 1 showed multiple ulcers. The malignant tumors consisted of 81 carcinomas of which 48 were carcinoma simplex and 25 adenocarcinoma, 4 sarcomas, of which 3 were lymphosarcomas and 1 a leiomyosarcoma, and 3 lymphomas. Of the latter 2 were classified as Hodgkin's disease and 1 as malignant lymphoma. The pathologic classification of all the lesions is given in Table V.

As has been pointed out by Lahey and Marshall, carcinoma of the stomach may be readily divided into two types: one the localized type which rapidly metastasizes to adjacent lymph nodes and the other the linitis plastica or leather bottle type in which the carcinomatous infiltration spreads through the muscle bundles in the gastric wall and makes a rigid but comparatively rarely metastasizing lesion which is appropriate for total gastrectomy.

The infiltrative and slowly metastasizing properties of lymphosarcoma also make the patient with this malignant growth a good risk for total gastrectomy. Patients with low grade malignant and benign lesions causing esophageal obstruction at the cardia also have yielded good results with this operation.

PREOPERATIVE BLOOD STUDIES

Much has been written about the effect of malignant disease of the stomach on the blood.

cases no anemia, or anemia of a mild degree was present. The general trend was toward hypochromia and even in those cases in which severe anemia was present a macrocytic by perchromic type was a rarity.

There was no characteristic picture in the number of white blood cells. The count varied from 3,050 to 16,800. In 21 per cent the counts were less than 6,000, in 42 per cent between 6,000 and 9,000, and in 37 per cent they were greater than 9,000.

PREOPERATIVE GASTRIC ACIDITY

The degree of gastric acidity preoperatively is shown in Table VII. No free acid was found in 68.9 per cent and in 89.6 per cent it was 25 units or less. A comparison of this series with a group of Lahey Clinic patients subjected to subtotal gastrectomy for carcinoma of the stomach shows a greater incidence of anacidity or low acidity in patients requiring total gastrectomy. On the other hand it is important to realize that an acidity of 50 units or greater is not incompatible with a lesion for which total gastrectomy is necessary. Unless this is constantly borne in mind, a sense of false security may result from the finding of an elevated acidity and operation may be delayed.

CAUSES OF DEATH

Immediate postoperative death. Twenty-six patients did not live to leave the hospital. The primary and contributing causes of death in so far as could be determined are listed in Table VIII. The postoperative deaths in the entire group are 26 or 29.1 per cent. From 1927 to January 1, 1942 there were 46 cases, with an operative mortality of 41.3 per cent. In the following 3 years and 9 months almost as many operations were performed (43) as in the previous 15 years. In this latter period, that is from January 1, 1942 to October 1, 1945 the

SIGNS AND SYMPTOMS FOLLOWING DISCHARGE

The signs and symptoms occurring in 57 patients following discharge from the hospital are shown in Table IX. Dysphagia is the most frequent difficulty encountered in patients who have undergone total gastrectomy. In this series it was reported in 28 per cent of those who survived the operation. In the majority of cases this is caused by scar tissue at the site of the jejunoesophageal anastomosis and is easily remedied by dilatation. In some instances 1 or 2 dilatations suffice to control the situation while in others 8 or more have been required at varying intervals. In some cases this symptom indicates a recurrence but of our cases it is thought that the patient died prematurely because her local physician felt that since the symptom very probably indicated recurrence dilatation was useless with the result that the patient died of starvation. Diarrhea was noted in 17 per cent. In several instances this symptom has been well controlled by adding hydrochloric acid to the diet. In others bismuth subcarbonate powder has been equally successful. This complaint in our experience is usually short lived and as the jejunal pouch enlarges, gradually disappears. Nausea and vomiting usually are early symptoms. The most frequent causes are nar-

operative mortality was 16.3 per cent. This phenomenal decrease is the result primarily of four factors (1) the increase in surgical skill arising from familiarity with the various techniques as well as the different problems encountered at operation (2) better selection of cases, (3) the introduction of new bacteriostatic agents chiefly the sulfonamides and penicillin and (4) better preoperative and postoperative care of the patient especially as to nutritional requirements and management of pulmonary and cardiovascular emergencies.

Subsequent deaths Of the 63 patients who left the hospital 43 were known to have died by March 1, 1946. The causes which are known in 35 of these are given in Table VIII. Recurrence developed in 85.7 per cent. This is interesting in view of the fact that the metastases in these cases showed malignancy in only 69.5 per cent. The discrepancy is probably more apparent than real.

rowing at the anastomosis which may be the result of edema or spasm or of the small initial capacity of the jejunal pouch. These symptoms yield frequently to antispasmodics and small and frequent feedings. The patient should be cautioned to eat slowly and to avoid any considerable amount of fluid with the meals. By systematically increasing the caloric intake over succeeding weeks, the capacity of the "new stomach" increases to a point at which three meals a day may be taken with comfort.

The failure to gain weight, which has been thought to be an almost inevitable sequel of total gastrectomy has not been conspicuous in our series. It appeared in only 12 per cent. When recurrence is the cause, any relief of necessity be temporary. From our experience, however this difficulty may be avoided in a large number of cases by dilatation and careful postoperative dietary management.

Fullness and abdominal distress, like nausea and vomiting are early symptoms and disappear with stabilization of the new physiological processes.

In our series insufficient blood studies were made postoperatively to generalize about the effect of the procedure except to state that a pernicious anemia like picture was very rare.

SURVIVAL CHANCE

The most important factor in determining the validity of an operative procedure is the chance which it provides the patient for survival in contrast to his life expectancy without surgical intervention. The operative survival in this series has already been discussed. The determination of the survival chance of those individuals who do not succumb to the operation is complicated by the facts that many individuals were subjected to this surgical procedure at a time when it had not been entirely perfected and that others have undergone operation too recently to be of statistical significance. For this reason, the survival chance has been calculated in two ways (1) based upon all the patients who have survived operation but have subsequently died, and (2) based upon all the patients who have survived operation whether now living or dead. The former calculations tend to give an underestimation of the probable present survival chance by virtue of the inclusion of operations performed during the early period. On the other hand the latter possibly also tends to give an underestimation because a number of cases are included in which the operation has been performed at a recent date and also because there is no way of predicting with certainty the survival chance of individuals who are still alive.

Table X lists the life expectancy of patients who have survived the operation. It is apparent that at least 50 per cent of the patients will survive for 12 months, 28 to 38.6 per cent will survive 18 months, 16 to 29.8 per cent will survive 24 months, and 9 to 21.1 per cent have a chance of living 3 years or more.

In our series 12 patients have survived 3 years or more. Eleven of these had a total gastrectomy performed for a malignant lesion of which 1 was a leiomyosarcoma, 1 a malignant lymphoma, and 2 lymphosarcomas. Of these 11 patients with malignant lesions, 5 had regional metastases at the time of operation as evidenced by the finding of invasion of the regional lymph nodes removed at opera-

50 F	4-1-43			Absent	Chronic gastritis

tion The longest survival was that of a 29 year old woman operated upon in 1937 for a leiomyosarcoma, who was living and well 8 years and 5 months after operation. Another patient, a 35 year old white woman was operated upon in 1939 for a lymphosarcoma with involvement of the regional lymph nodes and was living 7 years and 1 month after operation. She has recently been examined at an other hospital for a severe anemia character istic of pernicious anemia, and no evidence of recurrence was found. A third patient, a 64 year old white man with carcinoma simplex with microscopic metastases in the regional lymph nodes, was alive and in excellent health 5 years and 4 months after operation. A summary of all the patients surviving 3 years or more is given in Table XI.

POSTOPERATIVE NUTRITION

It is impossible to overemphasize the importance of nutritional care in the postoperative period of patients subjected to total

gastrectomy. In many instances if not in most, anorexia of varying duration has been a prominent symptom so that the patient is in negative nutritional balance at the time of operation. Consequently his intake has not been sufficient to maintain his daily requirements nor to build reserve for the operative period. In addition there may have been acute or chronic blood loss. Because operation must be performed as soon as the need for it is recognized the nutritional care in the postoperative period must provide adequate resources with which to promote wound healing ward off infection and preserve normal anatomical relationships which in tissues lacking normal tone owing to undernutrition and toxic effects are precarious.

In order to put the gastrointestinal tract as completely at rest as possible and so avoid stress at the suture lines nothing is given by mouth for at least 3 days. During this period whole blood is given as indicated. If shock threatens or intervenes plasma is given if

whole blood is not available or if hemoglobin and red blood counts show that whole blood is not required

A total of 1500 cubic centimeters of 10 per cent glucose, with 1 or 2 ampules of soluble vitamin B complex and 500 milligrams of vitamin C, is given on the first day with 1000 cubic centimeters of a protein digest. Approximately 3000 to 4000 cubic centimeters of fluid is given in the first 24 hour period depending on the patient's state of hydration. The difference between this requirement and the 2500 cubic centimeters already cited may be blood plasma, or 10 per cent glucose

The importance of limiting chlorides to actual requirements cannot be too frequently stressed. Although it is generally recognized that in the absence of vomiting, diarrhea, draining sinuses or profuse diaphoresis, the average daily requirement of sodium chloride is 5 grams, patients all too frequently receive from 12 to 25 grams during the early postoperative period. Such therapy often leads to localized or generalized edema, wound disruption and renal insufficiency

With the recent advent of protein hydrolyzates for parenteral administration there has become available a valuable addition to the postoperative nutritional care especially of patients undergoing gastrointestinal surgical procedures. The routine postoperative use of such preparations is of great importance in the promotion of wound healing, resistance to infection and prevention of edema. We advocate the administration of one of the available digests in amounts equivalent to at least 50 to 100 grams of protein daily until the patient is able to take adequate protein orally

It is extremely important to maintain the caloric intake during the period in which the patient is fed parenterally. This is provided by the liberal use of 10 per cent glucose. A daily regimen of 1000 cubic centimeters of a daily regimen of 1000 cubic centimeters of 5 per cent glucose and 2000 cubic centimeters of 10 per cent glucose with 500 cubic centimeters of normal saline solution provides 1200 calories, the approximate equivalent of 50 grams of protein and 85 grams of sodium chloride. This is continued

until the patient has been transferred to an oral dietary regimen. Also the patient is given parenteral vitamins as indicated previously

On the fourth postoperative day 1 ounce of water is given by mouth every hour. On the following day 1 ounce of malted milk or gel made with water is given hourly in addition to the water so that the patient takes something by mouth at half-hourly intervals. On the sixth and seventh days the amounts are increased by 1 ounce a day. On the eighth day a single feeding of soft solid food, such as soft egg cereal or custard is added. On succeeding days small additional feedings of soft solid foods are given until the patient is eating 6 meals a day of a high protein, high carbohydrate, low fat, and low residue diet. If the amounts of this diet are increased by approximately 300 calories a week, the jejunal pouch adapts itself in many instances so that within 6 months the patient is able to maintain weight and strength with 3 meals a day

SUMMARY

1. Eighty nine cases of total gastrectomy performed at the Lahey Clinic between 1937 and October 1, 1945 in patients ranging from 23 to 75 years of age, have been reviewed.
2. The postoperative mortality for the entire group is 29.1 per cent.
3. The postoperative mortality during the last 3 years and 9 months of the study during which 43 operations were done is 16.3 per cent.
4. Twelve patients have survived the operation for 3 years or more.
5. Calculation of life expectancy of patients surviving the operation shows that 50 per cent will survive 12 months or more, 38.6 per cent will survive 18 months, 16 to 29.8 per cent will live 24 months and 9 to 21.1 per cent will live 3 years or more.
6. A plan for postoperative nutritional care is presented.

Fig. 1. Achieving complete fecal diversion with a loop colostomy (A to F—steps employed in making the loop colostomy). A, The conventional way of dividing the exteriorized loop transversely to achieve fecal diversion. B, The result after complete division of the lumen of the proximal and distal loops are separated only by the thickness of the walls of the two apposed loops. C, The technique described here, employing glass rods and exteriorizing somewhat more generous segment. A slit has already been made in the gut wall, proximal to the first glass rod. In the presence of acute obstruction and distention, needle aspiration at this same site is performed on completion of operation and again in 6 hours, at which time a slit is made

in the bowel wall with cautery (usually) or knife to permit the introduction of a catheter as is shown here. In the absence of obstruction, the exteriorized gut ordinarily is not opened until about 7 hours after operation, allowing the wound to become sealed more effectively. D, The adhesive fastening of the rubber tube exposed over the ends of the glass rods is shown. This maneuver insures adherence of the exteriorized loop throughout the length of the incision. E, Unroofing the proximal orifice by an elliptical incision—more of the roof overlying the proximal orifice is removed than the distal. F, Following excision of a portion of the anterior wall of the exteriorized segment, the mucosa everts and becomes adherent to the skin.

porary colostomy warrants. Madelung achieved complete diversion by dividing the colon and

inverting the distal end. Kausch recommended placing an inflatable cuff in the distal segment,

Fig. (Continued—G to L—steps employed in closing the colostomy). G It is obvious that the separation of the proximal and distal orifices of the exteriorized segment is far better than that achieved by the conventional method of dealing with the loop colostomy. An incision is made in the skin 2 to 3 millimeters from the mucosal edge. H A running suture of fine catgut is employed to close the opened bowel transversely. I The wound's edges are painted with a local antiseptic and the wound is redraped. After the gut is freed up adequately, a single row of interrupted fine silk sutures (No. 0000) is placed to invert the

initial closure with catgut. J The bowel is dissected completely free from the parietal peritoneum, permitting return of the bowel to the peritoneal cavity. This same procedure gives assurance that the peritoneum and posterior rectus sheath can be sutured satisfactorily. K Suture of the posterior rectus sheath and peritoneum with interrupted sutures of silk (No. 000). L Closure of the anterior rectus sheath (silk No. 000). After closure of the peritoneum (K), the wound is washed out with liberal quantities of saline solution and again after closure of the anterior rectus sheath (L).

a method with which the writer too has toyed but without achieving complete diversion consistently. Baggio uses a pedicled strip of fascia

from the upper end of the wound which he pulls through the mesentery and ties about the ascending colon in making a cecostomy

Fig. 2. A, Photograph of an exteriorized transverse colostomy loop; a catheter has been placed in the proximal loop for decompressive purposes. B, Another similar loop of colostomy after unroofing; note how effectively the colic

orifices are separated. C, A sigmoid loop colostomy in the purpose of complete fecal diversion, which was made by the writer in a patient 9 years ago (D. B. University Hospital No. 62372).

TECHNIQUE OF THE PROCEDURE

The making of the colostomy. Inasmuch as complete fecal diversion is achieved regularly when the method is performed properly the colostomy may be employed as a temporary or even as a permanent measure. The usual temporary colostomy is made ordinarily in the right transverse colon as was described for acute colic obstruction a number of years ago. For irremovable cancers of the rectum presenting obstruction the same type of colostomy is performed on the sigmoid colon.

The technique of colostomy described previously (1936) is followed save in two particulars: (1) Two glass rods are drawn through the mesentery and placed beneath the exteriorized colon instead of one; the intent being to insure that the exteriorized segment of colon lies above skin level. (2) The colon is opened in the axis of the bowel and *not* transverse to its axis as is ordinarily done. Finally the proximal orifice is unroofed by cutting away an elliptical portion of the anterior wall (Fig. 1E).

Following this maneuver the two orifices of the bowel come to lie at opposite ends of the incision separated by the posterior bowel wall. Care should be observed not to cut away too generous a portion of the anterior wall lest thereby the subsequent closure of the colostomy be made difficult. The margins of the opened bowel evert and become adherent to the skin edges. Maintenance of the two glass rods in position at opposite ends of the wound until it is healed precludes retraction of the orifices of the bowel. The usual circumstance

is that shown in Figure 1G and Figure 1A. When the exteriorized segment of colon remains at skin level the two orifices remain at opposite ends of the wound. It is partial retraction of the colostomy within the abdomen which causes the orifices to remain patulous and permit dumping from the proximal into the distal orifice. Similarly employment of one glass rod in the middle of the exteriorized loop causes the orifices to become fixed in the wound at a lower level than is desirable in consequence of which fecal diversion is not complete. Patients with this type of colostomy are dismissed from the hospital 8 to 10 days after operation ordinarily; the general condition of the patient permitting with one or both glass rods still in place. Both glass rods usually are removed by the 14th postoperative day.

The skin incision is made parallel to the axis of the transverse colon and directly over it. In the patient with acute obstruction of the colon our practice is to tape a nickel over the umbilicus when the scout x-ray film is taken. This marker on the film serves as a landmark for the level of the incision. A transverse incision 10 to 12 centimeters in length directly over the right rectus muscle through all the layers of the abdominal wall permits even a distended colon to herniate out. Some surgeons have learned to their dismay that a distended transverse colon cannot be delivered through a vertical incision. When acute colic obstruction and distention are not present a shorter skin incision will suffice. The two

glass rods are drawn through avascular areas in the mesentery. The omentum is freed from the loop to be exteriorized and dropped back into the abdomen. The parietal peritoneum and posterior rectus sheath are approximated to fatty tags at the margins of the bowel with a number of interrupted sutures of fine silk (No 0000). No sutures are tied till all are placed. A smaller number of similar sutures are placed in the anterior rectus sheath approximating it to fatty tags at a higher level on the bowel. Finally a few sutures are placed similarly in the skin. If the bowel is acutely obstructed and distended a needle is inserted to measure intraluminal tension followed by aspiration. The exteriorized segment is covered with vaseline strips. In the presence of acute obstruction the bowel is aspirated again in approximately 6 hours. In any case every colostomy should be inspected for color and evidence of satisfactory viability 4 to 6 hours after completion of the operation. When obstruction is present a catheter is inserted into a small hole made proximal to the most proximally placed glass rod. Complete diversion usually is achieved even at this stage. A linear incision 3 to 3.5 centimeters in length is made in the axis of the exteriorized bowel with a bedside cautery 3 or 4 days after operation. The unroofing of the proximal orifice may be done at the same time or a few days later. The details of the operation are shown in Figure 1. The usual measurements of the colostomy opening when healing has occurred are 5 centimeters in length and 3 centimeters in width. Two centimeters of bowel wall intervene between the adjacent margins of the proximal and distal orifices. When the ordinary loop colostomy is divided completely in a transverse direction the two resultant orifices lie side by side. In patients with acute colic obstruction and distention the ultimate measurements of the exteriorized segment obviously are greater.

Closure of the colostomy The closure of such a colostomy is obviously simple. An incision is made in the skin adjacent to the bowel edges leaving a tiny rim of skin approximately 2 millimeters in width attached to the bowel. A running suture of catgut (No 000) closes the bowel transversely. The wound is pre-

pared again and the surgeon dons a new gown and gloves. The wound is enlarged and the peritoneal cavity is opened care being observed to separate the bowel from the margins of the wound all around and without injury to the bowel wall. A row of interrupted silk sutures placed over the catgut suture completes the closure. The wound is then closed with two layers of interrupted fine silk suture (No 000). After the peritoneum and posterior rectus sheath are closed the wound is washed out with a generous quantity of saline solution and again after closure of the anterior rectus sheath.

In the making of the colostomy as well as in its closure the patient routinely has an indwelling duodenal tube to which suction is attached. When the colostomy is opened the tube is withdrawn and after closure of the colostomy the nasal tube is withdrawn 48 to 72 hours after operation. The patient can be dismissed from the hospital ordinarily 5 or 6 days after operation. The writer does not consider succinylsulfathiazole or similar preparations a necessity for surgery of the colon. In primary reactions if the anastomosis is made properly such preparations are unnecessary as are also external diversionary decompressive vents. And if the anastomosis is made improperly all the drugs of the pharmacopoeia usually will not rectify the situation. If in the closure of the colostomy any surgical house officer feels strongly upon the subject of the virtues of succinylsulfathiazole in mitigating the effects of surgery imperfectly performed I am not averse to meeting his suggestion with an agreeable gesture. If he does not insist on it this refinement is omitted. It is important to know that it is the satisfactory closure of a colostomy that makes return of the colon to the peritoneal cavity a safe procedure a practice which this writer has followed routinely since 1929. A nice toilet of

When the bowel is ready for final closure, the surgeon may take out the temporary catgut suture. For 3 years, in making primary gastrotomies the writer has employed only a single row of interrupted silk sutures. Most of the surgeons in this clinic have adopted this technique as standard procedure in the making of anastomoses from the stomach to the cecum. A single row inversion made with interrupted sutures, without an inner row of continuous catgut assures wide and patulous orifices. Employment of a running stitch for the inner row causes puckering and consequent narrowing of the stomach.

the wound with the liberal use of generous quantities of saline solution makes it safe to effect primary wound closure with a reasonable assurance of the achievement of satisfactory healing

SUMMARY

A simple loop colostomy may be employed to secure complete fecal diversion. Employment of 2 glass rods, drawn through the mesentery beneath the bowel and maintained in position until the wound is healed, fixes the exteriorized loop in the wound above skin level. The colon is opened by a slit in the axis of the bowel and the proximal orifice is unroofed by cutting away a small portion of the anterior wall. Such a colostomy is easy to make as well as to close and presents all the

advantages of the more formal procedures in achieving complete fecal diversion.

THE HYPERFUNCTIONING SINGLE ADENOMA OF THE THYROID

OLIVER COPE, M.D. RULON W. RAWSON, M.D. and JANET W. McARTHUR, M.D.
Boston, Massachusetts

IT is accepted that hyperfunction of an endocrine gland is associated with either a neoplastic or hyperplastic anatomic change. Neoplasia and hyperplasia, clearly differentiated by definition, have proved difficult to distinguish pathologically in disorders of the thyroid gland associated with hyperfunction. The debate as to whether the lesion of nodular goiter with hyperthyroidism is truly adenomatous or merely represents a late and lumpy stage of diffuse hyperplasia has long raged. The debate exists perhaps because there is no true difference between neoplasia and hyperplasia of the thyroid gland but more likely because the pathologist has lacked tools by which the differentiation can be made.

In disorders of certain other endocrine glands associated with overactivity, the problem of differentiating pathologically between neoplasia and hyperplasia is less confused. The division of the parathyroid system into four separate glands renders the gross recognition of the distribution of anatomic disease simpler than in the thyroid. The common type of anatomic change of the parathyroids encountered in hyperparathyroidism is that localized to but one of the four glands. The diseased tissue is then considered to be neoplastic and is called an adenoma. The distinct separation of the adrenal cortical gland into two parts offers a similar advantage.

The existence of a single adenoma of the thyroid causing hyperfunction, comparable to that found in patients with hyperparathyroidism, has been suggested (11), questioned (16) and not proved. Certain it is that the commonest type of anatomic disorder of the thyroid gland associated with hyperthyroidism, whether it be called hyperplasia, nodular or adenomatous goiter, diffusely involves the

thyroid gland. So usual for the thyroid is this diffuse involvement that when a single adenoma is found in a patient with hyperthyroidism, one must be certain that smaller adenomas are not hidden elsewhere in the thyroid gland.

It might be of academic interest only to establish whether a single adenoma of the thyroid is ever associated with hyperthyroidism as it is in the parathyroid with hyperparathyroidism but its establishment should prove of practical value since it would offer a chance to learn about the functional capacity of adenomas and improve the judgment in therapy. With the advent of the two medical therapies, thiouracil (1) and radioactive iodine (2, 7) it is imperative to know not only whether the early relief of the hyperfunction of neoplasia is the same as of the hyperplastic type of the disease but more especially whether eventual malignant degeneration, about which apprehension is proper, will prove unequally evil in the two types.

Since the pathologist, using the conventional histologic methods, has not been able to tell us the degree of functional activity of the thyroid cell, we need criteria to establish the existence of a single adenoma of the thyroid with hyperfunction.¹ Clinically, we should take for granted symptoms of hyperthyroidism and an elevated metabolic rate which are relieved by operative removal of the adenoma. There is in addition anatomic and biologic evidence which the surgeon can divulge and two laboratory tests which can be applied. The laboratory tests include inactivation of thyroid stimulating hormone of explanted thyroid tissue and radioactive iodine absorption by the thyroid gland.

Certain special cytologic methods, demonstrating the Golgi apparatus, mitochondria, and secretory droplet, have been introduced which are believed by many to indicate the functional activity of the thyroid cell. These methods require techniques which have proved not feasible in the routine pathological laboratory.

*Patient also received X-ray treatment; there was no effect on the metabolic rate.

**Patient also received and did respond to thionin.

***Patient developed toxic reaction to thionin. Also received X-ray treatment without effect.

If an adenoma involving only one portion of the thyroid apparatus, is hyperfunctioning and is the sole source of the hyperfunction then theoretically the remainder or uninvolved portion of the thyroid should not be normal but functionally resting and anatomically atrophic. Attention has already been called to the atrophy of the uninvolved parathyroids in hyperparathyroidism associated with an adenoma (3) and of the contralateral adrenal cortex in the patient with an adrenal cortical adenoma with hyperfunction. Such an atrophy of the thyroid gland has been shown to occur in animals which have been rendered thyrotoxic by large doses of thyroid extract and has been observed by us in one patient¹ who had taken large doses of thyroid extract and whose thyroid gland was exposed at operation under the mistaken diagnosis of Graves

disease. Such atrophy of a gland has been called an atrophy of disuse.

OBSERVATIONS

During the past 10 years 10 patients have been cared for in the Thyroid Clinic at the Massachusetts General Hospital whose thyroid glands fulfill the anatomic and biologic criteria of an hyperfunctioning single adenoma of the thyroid. Data regarding the nature of the disorder of these 10 patients are given in Table I. The patients were of varying ages, but one of the patients was male. All had symptoms and metabolic evidence of hyperthyroidism: a positive lid lag and stare were present in 5. In only one was there any suggestion of exophthalmos. The severity of the disease varied from crippling to a mild disability.

The 40-year-old daughter of a woman's college is cared for this hospital as a case of hyperthyroidism. She reported that she had been concerned about her obesity and some months previously had succeeded in losing weight by strenuous dieting. Examination disclosed the signs typical of hyperthyroidism: goiter of moderate size, very except for the absence of palpable nodules. She had bright staring eyes with positive lid lag, fine tremor, rapid pulse and widened pulse pressure. Her basal metabolic rate was +40. In spite of the absence of palpable nodules diagnosis of Graves disease was made, believing it to have been induced by the rapid loss of weight. I was advised that the patient was hidden

behind the mask of hyperthyroidism. She was placed on potassium iodide and she apparently made prompt response; her basal metabolic rate was +14 in 7 days. At operation she proved not to have a single adenoma; the thyroid gland was small, soft, avascular (thyroid carcinoma was reported). The portion of each lateral lobe removed had microscopic evidence of "involution" by the pathologist. Confirmed hyperthyroidism was not found; postoperatively the patient continued with this response of "involution" by the pathologist. I was advised that the patient was hidden behind the mask of hyperthyroidism. She was placed on potassium iodide and she apparently made prompt response; her basal metabolic rate was +14 in 7 days. At operation she proved not to have a single adenoma; the thyroid gland was small, soft, avascular (thyroid carcinoma was reported). The portion of each lateral lobe removed had microscopic evidence of "involution" by the pathologist. Confirmed hyperthyroidism was not found; postoperatively the patient continued with this response of "involution" by the pathologist. I was advised that the patient was hidden behind the mask of hyperthyroidism. She was placed on potassium iodide and she apparently made prompt response; her basal metabolic rate was +14 in 7 days. At operation she proved not to have a single adenoma; the thyroid gland was small, soft, avascular (thyroid carcinoma was reported). The portion of each lateral lobe removed had microscopic evidence of "involution" by the pathologist. Confirmed hyperthyroidism was not found; postoperatively the patient continued with this response of "involution" by the pathologist.

CASE 4 (See Fig 4 and Charts 4a and b) A 33 year old woman was admitted to the hospital complaining of a gradually enlarging goiter of 7 years duration. Although the patient had no difficulty in swallowing she was constantly aware of a sensation of pressure in the neck. During the months immediately prior to admission she had noticed slight trembling of her hands and pounding of her heart when she lay on her left side at night. Hungry all the time she had gradually been gaining weight for several months. She had not experienced nervous irritability, heat intolerance, dyspnea, or change in bowel habit.

On examination the patient displayed a slight tremor of the extended fingers. The hands were warm but not excessively moist. There were no eye signs. A firm nontender rounded nodule, 5 centimeters in diameter was palpable in the upper portion of the left thyroid lobe. The isthmus and right lobe of the thyroid could not be felt. Basal metabolic rates of plus 19, 21 and 24 were obtained. A diagnosis of thyrotoxicosis probably due to a hyperfunctioning adenoma was made. Saturated solution of potassium iodide 5 drops twice daily was prescribed and the patient discharged home to be readmitted for operation.

When readmitted 2 weeks later she stated that the only symptomatic change was a decrease in the sensation of pressure in the neck. Her weight had remained stationary. At operation the left lobe of

Fig 1 The hyperfunctioning adenoma and atrophic uninvolved thyroid tissue in Case 1. The encapsulated adenoma is considered to have been the source of the excessive hormone production because the uninvolved tissue was grossly and evenly atrophic. There was a bit of the uninvolved thyroid tissue at both upper and lower poles of the adenoma, all that remained of the right thyroid lobe. The separate, shrivelled piece of tissue represents the entire isthmus and anterior half of the left thyroid lobe. (For the effect of the adenoma on metabolic rate, see Chart 1.)

Chart 1 The effect on metabolic and pulse rates and weight of extirpation of the single adenoma of Case 1 (Fig. 1). Bed rest, but probably not iodine, was followed by partial subsidence of the thyrotoxicosis immediately before the operation. The depressed metabolic rate found soon after operation proved to be transient.

Chart The effect on metabolic and pulse rates and weight of excision of the single adenoma of Case 2 (Figs. 2a and b). It is possible that iodine and bed rest together induced the partial remission of the hyperthyroidism prior to operation.

the thyroid was found to consist largely of a solid tumor measuring 5 by 4 by 3 centimeters. At the posterior portion of both the upper and lower poles, there was a small mass of uninvolved atrophic tissue. There was also a rim of atrophic thyroid on the medial side of the adenoma and on the anterior surface of the trachea. The isthmus tissue was so thin as to be hardly recognizable. The right lobe was also atrophic, measuring 3 by 2 by 1 centimeter. Microscopically the adenoma showed hyperplasia and involution. Biopsies of the uninvolved tissue on the left side and of the right lobe were consistent with involution.

Postoperatively the patient was less restless than before and no longer conscious of the beating of her heart. Her appetite was less voracious but her

weight remained stationary. The basal metabolic rate 6 weeks after operation was minus 14; 12 months later minus 14.

In Table II for comparison with the patients having single adenomas and hyperthyroidism are given the data on one patient with a large adenoma and two small satellite adenomas associated with hyperthyroidism and three patients with single adenomas but no hyperthyroidism. These latter three have been selected from a group of 15 patients with single nodules and no hyperthyroidism in whom radioactive iodine studies have been carried out.

Gross anatomy. At operation on the 10 patients with single adenomas and hyperfunction the anatomic lesion was found to be circumscribed. In 8 patients the lesion was confined within a clearcut capsule involving only one part of a lateral lobe as in Cases 1 and 2 (Fig. 1 and 2b). In the other 2 patients, Cases 3 and 9, (both elderly and with longstanding disease), the lesion involved the entire lateral lobe, there being no uninvolved tissue recognizable on that side (Fig. 3b). In all 10 patients the uninvolved tissue was grossly consistent with atrophy. The uninvolved residual of the lateral lobe of the 8 cases, and the isthmus and the contralateral thyroid lobe of all 10, were smaller than the expected normal and in some cases were shriveled (Fig. 1 and 2b). In all cases the uninvolved tissue varied from the normal, it was softer and more pliable, the surface convolutions were less prominent or absent, the color was a little paler and speckled with white, the vessels were less prominent, and on cut sections the tissue was judged to be less

Fig. 2a. Case 2. There is no exophthalmos or stare. Loss of weight is apparent. The retraction of the lower end of the right sternomastoid muscle by the adenoma in the left lobe of the thyroid is visible. (The thyroid adenoma removed and its effect on the metabolic rate are shown in Figure 2b and Chart 2.)

Fig. 2b. The hyperfunctioning adenoma and rim of atrophic uninvolved tissue of Case 2. The adenoma was encapsulated, firm, fleshy and brown while the uninvolved thyroid tissue was soft, diffusely shriveled and avascular. The adenoma is considered to have been the source of the excessive hormone production because of the gross atrophy of the uninvolved portions of the thyroid gland and because its removal resulted in relief of the hyperthyroidism (See also Fig. 2a and Chart 2.)

vascular. So soft was the gland in 1 or 2 cases that the thyroid and cricoid cartilage could be felt through the thyroid tissue. In no instance was a second nodule seen or felt at operation.

In the 4 control patients the anatomic findings at operation differed significantly. The first patient whose data are summarized in Table 11, Case 1C, was believed preoperatively to be one whose hyperthyroidism was due to a single adenoma. The hyperthyroidism was definite and but one nodule was palpable on physical examination in the region of the thyroid gland. At operation the uninvolved tissue however was not atrophic. The isthmus and lobe contralateral to that containing the preoperatively palpable nodule were fully as large, firm and vascular as normal and further scrutiny disclosed two small nodules in the posterior position of the contralateral lobe. The large nodule was excised *in toto* and a small portion only of the contralateral lobe was taken for microscopic section and thyroid stimulating hormone inactivation study.

CASE 1C. A 23 year old woman was admitted to the hospital complaining chiefly of nervousness of 12 months' duration. She had been well until about one year prior to admission when without obvious cause she became irritable and easily upset. Six months before admission she first noticed a swelling in her neck which slowly increased in size. Three months prior to entry she began to experience palpitation, exertional dyspnea, increased frequency of bowel movements and excessive perspiration. She felt increasingly fatigued and gave up bowling, swimming and dancing. Her weight remained stationary despite a noticeably increased appetite.

On examination she appeared warm, sweaty and flushed. There was a slight tremor of the extended fingers. No eye signs could be elicited. The left lobe of the thyroid was replaced by a soft nodule measuring 5 by 7 centimeters which displaced the trachea to the right and extended down to the sternal notch. A small amount of tissue was palpable to the right of the trachea in the thyroid region. The pulse was 110 and bounding in character. Basal metabolic rates of plus 28, 24, and 30 were obtained. A diagnosis of thyrotoxicosis possibly due to a hyperfunctioning adenoma was made. After 2 weeks of therapy with potassium iodide 15 drops a day the basal metabolic rate had fallen to minus 6 and the patient's weight had increased 2.5 kilograms. She was discharged home on iodine therapy to be followed in the out-patient clinic.

Five months later she was readmitted for excision of the nodule because of its increase in size. She had taken the iodine faithfully and felt less nervous. Her tremor and frequent bowel movements continued.

Fig. 3a. Case 3. The calm expression belies the presence of hyperthyroidism. The unilateral goiter subsequently removed is shown. In Figure 3b and its effect on the metabolic rate in Chart 3.

Fig. 3b. The left-sided goiter and biopsy specimen of the atrophic right thyroid lobe of Case 3. The entire left lobe of the gland was involved in the anatomic disorder but a section the disorder proved to be uneven. In the upper lobe was a smooth nodule, the tissue of which is comparable to the homogeneous adenomas (illustrated in Figures 1, 2b, and 4). The remainder of the goiter was made up of irregular whorls of cellular thyroid tissue; the septa are indistinct. The entire isthmus and right thyroid lobe were atrophic. A similar, irregular and unilateral goiter with simple uninvolved tissue elsewhere was encountered in Case 6. The adenomas of the 8 other cases are of the homogeneous type. (See also Figs. 3a and Chart 3.)

and her weight remained approximately stationary. The physical findings were essentially unchanged except that the nodule in the left lobe of the thyroid seemed larger measuring 7 by 7 centimeters. Basal metabolic rates of plus 46, 43 and 35 were obtained. After a month's bed rest the rate had fallen to plus 12. At operation the left lobe was found to contain a large nodule and the otherwise normal appearing right lobe to contain two small nodules. The nodule in the left lobe was resected in entirety leaving about 4 grams of uninvolved apparently normal tissue. A biopsy specimen was taken of the uninvolved normal appearing tissue of the right lobe. Microscopically all sections of the left lobe nodule showed involution. The tissue removed from the right lobe was consistent with normal.

Postoperatively the patient gained 5 kilograms in weight and was entirely relieved of her symptoms. The basal metabolic rate 10 days after operation was minus 10.

The remaining 3 control patients of Table II whose thyroid function is considered to have been within normal limits were each found at operation to have a single adenoma. The uninvolved tissue was considered to be consistent with normal but in the last Case 4C the note was made at operation that the uninvolved parts of the gland were on the small side of normal and unusually soft. Partial atrophy was considered possible. The results of the radioactive iodine determinations in this case were therefore not surprising (see below under Radioactive Iodine Uptake).

Microscopic anatomy. The tumors of all 11 cases, that is including the control cases, were variously classified and without any correlation with function by our pathologists as involutonal nodules involution and hyperplasia, hyperplastic adenoma and struma nodosa micro et macro folliculare. The biopsy of the uninvolved tissue was described as either normal or involution, there being no correlation with the gross finding of atrophy.

Operative relief. All 10 of the patients with single adenomas and hyperfunction were relieved of the thyrotoxicosis by operation. Operation in each case consisted of total excision of the adenoma and resection of a certain amount of the atrophic uninvolved tissue. In the first 2 cases, the isthmus and approximately half of the contralateral lobe were resected (Fig. 1 and 2b) in the others only a small portion of the atrophic tissue was removed as a biopsy (Fig. 3b and 4).

There was a transient drop in metabolic rate to subnormal levels immediately following operation in 3 of the 7 patients in whom an adequate number of determinations were made (Charts 1, 2 and 4a). In a fourth Case 8, the

Chart 3 The effect on metabolic and pulse rates and weight of extirpation of the unilateral lobe of Case 3 (Figs. 3a and b). Both iodine and roentgen irradiation failed to induce a remission of the thyrotoxicosis.

metabolic rate remained subnormal but there were no signs or symptoms of hypothyroidism.

The transient period of hypometabolism following operation suggests that there may have been functional inactivity of the uninvolved tissue. Permissible in Cases 1 and 2 in whom the more radical resection was done the fall should not have occurred in the other if the uninvolved tissue was normal physiologically. Removal of one of two normal lateral thyroid lobes at parathyroid exploration which had been carried out in several of our hyperparathyroidism cases has not been followed by any such decrease in thyroid function. The ultimate return of the metabolic rate suggests capacity of the uninvolved tissue to recover and retain normal function. This is in support of the view that such atrophic tissue is not diseased but suffers only from disorder of function.

Thyroid stimulating hormone inactivation. The adenomatous and uninvolved atrophic

tissues of 2 patients with single adenomas and hyperthyroidism (Cases 4 and 7) and of the one patient with multiple adenomas with hyperthyroidism (Case 1C) have been studied for their ability when explanted to inactivate the thyroid stimulating hormone of the anterior pituitary gland. This action has been used as a test by Rawson, Graham and Riddell to differentiate between normal and various pathologic human thyroid tissues (13, 14). A slice of thyroid tissue weighing approximately 150 milligrams is incubated for 24 hours in a substrate containing 7.5 units of thyroid stimulating hormone (Junkman and Schoeller guinea pig units). Upon removal of the thyroid tissue the residual activity of thyroid stimulating hormone is measured by the effect of the substrate upon the mean cell height of the thyroid gland of the injected baby chick.

It has been found that an explant of normal human thyroid tissue inactivates 3.5 units (14) (Chart 3, diagram 1). (The normal thyroid

Chart 4a. The effect on metabolic and pubic rates and weight of removal of the single adenoma of Case 4 (Fig. 4 and Chart 4b). Iodine failed to produce a remission of the thyrotoxicosis.

tissue was removed from 7 patients undergoing parathyroid exploration for hyperparathyroidism). The portions of diffuse hyperplasia resected from 20 patients with hyperthyroidism who were prepared for operation with iodine inactivated all of the thyroid stimulating hormone present in the bathing fluid (Chart 5 diagram 2).

A portion of the adenoma removed from Case 4 (patient with a single adenoma and hyperthyroidism) was found to inactivate all of the thyroid stimulating hormone (Chart 5 diagram 3). The piece of the uninvolved atrophic thyroid tissue resected from the same patient was found to inactivate none of the hormone (Chart 5 diagram 4). Similar findings were obtained in the tissues removed from Case 7.

The failure of the grossly atrophic, uninvolved tissue found in the presence of a single adenoma in the patients with hyperthyroidism to inactivate thyroid stimulating hormone suggests that there has been a prolonged absence of the stimulus to produce thyroid hormone. The rate of inhibition of anterior pituitary stimulation of the thyroid gland by an excess of thyroid hormone has been discussed elsewhere (15).

The results on the tissues resected from the patient with the multiple adenomas with hyper-

Chart 4b. Inactivation of thyroid stimulating hormone by explanted thyroid tissue. The thyroid tissues tested were: (1) normal, being pieces of glands removed at para thyroid exploration from 7 patients with normal metabolic rates; (2) hyperfunctioning hyperplastic, consisting of portions of diffuse goiter resected for hyperthyroidism in 20 patients prepared for operation with iodine; (3) hyperfunctioning adenomatous; and (4) its associated grossly atrophic uninvolved tissue from Case 4. The patient was relieved of the hyperthyroidism by resection of the adenoma and biopsy only of the uninvolved tissue. (See also Fig. 4 and Chart 4a.) The patient received iodine before operation. Explants were sliced and trimmed to weigh approximately 50 milligrams. Beef antuitrin-T was used.

thyroidism (Case 1C) showed complete inactivation by the large adenoma but only normal inactivation by the nonadenomatous tissue from the contralateral thyroid lobe. This lobe was not grossly atrophic. The finding of normal inactivation by the grossly normal tissue of a patient with active hyperthyroidism indicates either that all normal tissue is not put at physiologic rest and therefore does not undergo atrophy in the presence of an hyperfunctioning adenoma or that what was grossly compatible with and believed to be normal tissue in this patient was really diseased. The presence of the two small satellite adenomas in the contralateral lobe is in favor of the latter.

Radioactive iodine uptake. The second laboratory method of judging objectively the physiologic or secretory activity of thyroid tissue is the measurement of the amount of uptake of radioactive iodine (4, 5, 6). As might be anticipated the amount of the radioactive isotope absorbed in the thyroid is proportional to the secretory activity of the gland. It has been found that the thyroid gland of a normal person given a small or tracer dose of radioactive iodine will absorb approximately 40 per cent

of this iodine in the first hours and that the other 60 per cent will appear in the urine with in 48 hours. It has also been established that the avidity for iodine is increased in the hyperplastic thyroid of a patient with exophthalmic goiter¹ In such hyperplasia associated with increased activity 80 to 90 per cent of the administered iodine is collected in the thyroid substance and only 10 to 20 per cent is excreted in the urine in the first 48 hours. In contrast in a patient with a hyperplastic goiter and hyperthyroidism under treatment with thiouracil the absorption of iodine is partially blocked. Less than 20 per cent of the radioactive iodine injected is held by the thyroid while more than 80 per cent passes out through the kidney in the first 48 hours (17). The initial observations of such iodine absorption by the thyroid determined by Geiger counter scrutiny of the neck and measurements of the actual urinary excretion have been checked recently by direct measurement of the radioactive iodine content of thyroid tissue surgically removed as a biopsy (8 to 17).

The radioactive iodine absorption by thyroid tissue has been measured in one patient with a single adenoma and hyperthyroidism (Case 8) and in 15 patients with single nodules without thyrotoxicosis. The radioiodine content of both the tumor and uninvolved tissues has been measured. The radioactive iodine has been given to the patient by mouth 1 to 7 days before operative extirpation of the glandular tissue. The adenoma of the case with hyperthyroidism showed an avidity for iodine comparable to that found in untreated hyperplastic goiter with hyperthyroidism while the uninvolved grossly atrophic tissue failed to take up any measurable quantity of radioactive iodine (Chart 5, diagram 4 and Chart 6, diagram 4). These findings strongly suggest that indeed on present knowledge indicate that the entire output of hormone was from the adenoma and that the adenoma therefore must have been responsible for the thyrotoxicosis.

Study of the 15 adenomas not associated with hyperthyroidism indicates that adenomatous tissue varies in its functional activity.

The tracer dose of iodine contains approximately 50 micrograms of iodine, an amount known to be too small to influence the function of the gland. This amount is a small portion of the daily excretion of iodine and an even smaller proportion of the content of iodine of the gland.

Fig. 4. The hyperfunctioning adenoma of the left thyroid lobe and biopsy specimen from the atrophic right lobe of Case 4. The adenoma was sectioned, a piece removed from the anterior half and then the halves were replaced. The exposed cut surface of the posterior half shows the adenoma to be of the homogeneous cellular type with a single clearly demarcated capsule. There is a small remnant of shrivelled uninvolved thyroid tissue on the lateral surface of the adenoma. The effect on metabolic rate of its removal, the inactivation of thyroid stimulating hormone by it and the atrophic uninvolved tissue are shown in Charts 4a and b.

Three examples have been chosen from the 15 patients to illustrate the distribution in activity and are shown together with the case with hyperthyroidism in Chart 6. In the first labelled 3, the uptake of radioactive iodine and therefore the hormonal secretory activity is minimal while that of the uninvolved tissue is normal. The ratio of the uptake of uninvolved to adenoma is 23:1. In the second case with normal hormonal output the ratio of uptake of the uninvolved to adenoma is but 7:1. The avidity of the uninvolved is near the minimal amount expected of normal tissue. The activity of the adenoma is still below that of normal tissue. This case is labelled 3A. The diagram labelled 3B depicts a reversal of the ratio of uptake of iodine in a patient with overall normal thyroid activity. In this case the uptake of iodine per gram of thyroid tissue was considerably more in the adenoma than in

Chart 5. Proportionate size configuration, and radioactive iodine uptake of normal and diseased thyroid glands. The intensity of the shading indicates the avidity of the tissue for a tracer dose of iodine. Diagram 1 represents normal gland. Diagram 2 is that of a patient with diffuse hyperplasia with hyperfunction (Graves disease). It is therefore drawn diffusely larger than the normal and colored blacker because of an increased avidity for iodine. Diagram 3 represents a single adenoma with but little iodine uptake in a patient with normal thyroid function, the uninvolved gland is normal in size and iodine uptake (Case 2C, see also Chart 6 diagram 3). Diagram 4 represents the findings in Case 8. It is a single hyperfunctioning adenoma. The adenoma absorbs an increased amount of iodine, like the uninvolved takes up none. The uninvolved tissue is atrophic and shrunken. (See also Chart 6 diagram 4).

the uninvolved tissue. The ratio of uninvolved to adenoma was 1:23. This finding coupled with the gross appearance of the uninvolved tissue which was consistent with partial atrophy, suggests that the adenoma was secreting the large part of the hormone requirements of the patient and that the uninvolved tissue was at partial rest. The findings in these 3 cases are to be contrasted with diagram 4 which depicts the patient with hyperthyroidism (Diagrams 4 of Charts 5 and 6 are of the same patient.) In this case the given ratio of 1:715 is arbitrarily set by the sensitivity of the method since there was no measurable radioactivity in the uninvolved tissue.

Comparison of these 4 cases suggests first that secretory activity of an adenoma is not all or none but that there are many gradations; second that if the secretory activity of the adenoma is high and the size of the adenoma sufficient hyperthyroidism results; and third that such hyperthyroidism is accompanied by depression of the activity of the uninvolved gland.

Responses to iodine, thiouracil, and irradiation. It is not clear that the hyperthyroidism of any of the patients was alleviated as a result of the administration of iodine. The metabolic rate fell in 6 patients following iodine but it is possible that the fall was the result of contin-

Chart 6. Gradations of function of thyroid adenomas indicated by their absorption of a tracer dose of radioactive iodine. The intensity of the shading is proportionate to the avidity of the tissue for the iodine. The measured iodine uptake of each tissue is given below the diagram; the figures represent the per cent of the dose of iodine found per gram of tissue. The ratio of iodine uptake of uninvolved tissue to adenoma is given in the lowest line of figures. In the first three diagrams (1, 2A, and 3B) the overall thyroid function was normal yet the activities of the adenoma and uninvolved tissues differed. In diagram 3, we give the findings in Case 2C (see also Chart 5, diagram 3), in diagram 2B those of Case 2C, and in diagram 3B those of Case 2C. With increasing adenoma function there is decrease in the function of the uninvolved tissue. In all cases decrease in size or partial atrophy in diagram 3B as compared with diagram 3. Diagram 4 represents the finding in Case 8 (see also Chart 5, diagram 4) with a hyperfunctioning adenoma; there was no uptake of iodine by the atrophic uninvolved tissue.

ued bed rest or other cause (Charts 1 and 2). Certain it is that there was no response in the other four (Chart 4a).

The adenomas of 2 patients, Cases 3 and 4, were exposed to roentgen irradiation before operation. In neither case was this treatment followed by any change in the metabolic rate.

Only one of the 10 patients was treated with thiouracil, Case 5; neither the inactivation of thyroid stimulating hormone nor radioactive absorption was measured in this patient's gland. The thiouracil was accompanied by a drop of 23 per cent of the metabolic rate in 14 days. A response to thiouracil is to be anticipated part of the fall in this patient may have been due to rest. The patient at a previous hospital admission had made an apparent response to iodine which had then been omitted for some months prior to the thiouracil treatment.

FURTHER COMMENT

The gross anatomic findings and the tests of function, inactivation of thyroid stimulating hormone and collection of radioactive iodine, have delineated the single adenoma with hyperfunction as a disease entity of the thy-

roid gland. Not only does the adenoma inactivate an excess of the anterior pituitary hormone but it has been shown to be the only part of the thyroid gland which absorbs iodine. Since iodine is a chemical requisite of the thyroid hormone the adenoma is the only part forming hormone and must therefore be responsible for the excess. The uninvolved tissue which collects no iodine and inactivates no pituitary stimulating hormone is apparently at physiologic rest and is anatomically atrophied. Thus, the term adenoma used to denote a benign neoplasm has been given a physiologic as well as anatomic meaning. Strictly neoplasia means an abnormal growth of tissue which takes place without regard to the laws governing the normal portions of the gland. In these cases the excessive function has been assumed by the adenoma indicating a disordered secretory activity in addition to the pathologic cell growth. In contrast the uninvolved tissue obeys physiologic laws and rests in the presence of an excess of the hormone; its disorder of function is secondary and the tissue is not in itself diseased.

The single adenoma is a rare cause of hyperthyroidism. It is best considered as a pathologic type at the extreme from the diffuse hyperplasia which is the common type associated with hyperfunction. The disease types in the thyroid and parathyroid glands are thus reversed.¹ As with hyperparathyroidism due to adenoma, hyperthyroidism may also be associated with more than one adenoma. We have encountered 2 cases with two adenomas each. That the neoplasms or adenomas were the cause of the hyperfunction is indicated by the accompanying atrophy of the uninvolved tissue comparable to that found in the cases with the single hyperfunctioning adenomas described in this paper. Doubtless cases will be found in which there are multiple adenomas.

NOTE: Cases of hyperparathyroidism proved by operation. 1. The Massachusetts General Hospital, 75 have had the localized form of autonomic disorder. 170, one gland only has shown anatomic abnormality and in none of these has even the whole gland been involved. 1. The disease process, small run of uninvolved parathyroid tissue has surrounded the diseased tissue. In 5 of the 75 cases, 19 glands, rather than only one, have shown changes; the other two glands of each patient are not involved. Because of the localized nature of the disease, these 75 cases the lesion has been considered neoplastic and has been called an adenoma.

In 7 of the 85 cases of hyperparathyroidism the disease process has involved all of the tissue of 11 of the parathyroid glands and has been termed hyperplasia by some and hyperplasia by others. That the disease process is considered different from that of the localized neoplasia or adenoma is strengthened by the fact that the clinical arrangement of the hyperplastic glands differs distinguishably from those of the cells found in the adenomas.

all hyperfunctioning. The differentiation of the lumps as true neoplasms will depend upon the demonstration of physiologic rest of the uninvolved tissue in contrast to hyperfunctioning paranodular tissue of nodular goiter with hyperthyroidism (12). Indeed henceforth distinction between lumpy diffuse goiter with hyperthyroidism and true neoplastic or adenomatous goiter must be made by simultaneous scrutiny of all the nodules and the uninvolved or paranodular tissue.

The observation that the disease process in the thyroid is localized to one part of the gland suggests that the origin of the disease is different from that of the diffuse hyperplasia type in which all of the tissue is acting beyond normal physiologic control. Our studies give no clue as to the nature of the initiating process. It is of interest that the clinical disease produced by the hyperfunctioning single adenoma did not differ significantly from Graves disease with the diffuse goiter. There is a suggestion that eye signs, particularly exophthalmos, were less frequently encountered but the number of cases is too small to be sure that this difference was not due to the age of the patients. That the function of the majority of the adenomas was not affected by iodine is certain.

Of significance to the surgeon is the finding that the uninvolved tissue obeys physiologically the law of supply and demand as far as function is concerned and is therefore not diseased. Nothing is to be gained by excising it. Indeed it would be better to leave all of it behind, the better to insure more prompt and complete return of function. If the surgeon is familiar with tissue atrophied by disease little difficulty will be encountered in recognizing it.

We have not had an opportunity to test the efficacy of radioactive iodine in therapeutic doses in reducing the secretory activity of a hyperfunctioning adenoma. Presumably it should prove effective though the failure of roentgen irradiation in the 2 cases in which this latter agent was employed suggests that larger doses of radioactive iodine might be needed than in Graves disease with diffuse hyperplastic goiter. It is not surprising that thiouracil was effective in lowering the metabolic rate in the patient in whom this drug was

Chart 5. Proportionate size, configuration, and radioactive iodine uptake of normal and diseased thyroid glands. The intensity of the shading indicates the avidity of the tissue for a tracer dose of iodine. Diagram 1 represents normal gland. Diagram 2 is that of a patient with diffuse hyperplasia with hyperfunction (Graves disease). It is therefore drawn diffusely larger than the normal and colored blacker because of an increased avidity for iodine. Diagram 3 represents a single adenoma with but little iodine uptake in a patient with normal thyroid function; the uninvolved gland is normal in size and iodine uptake (Case 2C, see also Chart 6, diagram 3). ued bed rest or other cause (Charts 1 and 2). Certain it is that there was no response in the other four (Chart 4a).

The adenomas of 2 patients, Cases 3 and 4, were exposed to roentgen irradiation before operation. In neither case was this treatment followed by any change in the metabolic rate.

Only one of the 10 patients was treated with thiouracil. Case 5, neither the inactivation of thyroid stimulating hormone nor radioactive absorption was measured in this patient's gland. The thiouracil was accompanied by a drop of 23 per cent of the metabolic rate in 14 days. A response to thiouracil is to be anticipated; part of the fall in this patient may have been due to rest. The patient at a previous hospital admission had made an apparent response to iodine which had then been omitted for some months prior to the thiouracil treatment.

FURTHER COMMENT

The gross anatomic findings and the tests of function, inactivation of thyroid stimulating hormone, and collection of radioactive iodine, have delineated the single adenoma with hyperfunction as a disease entity of the thy-

roid gland. Not only does the adenoma inactivate an excess of the anterior pituitary hormone but it has been shown to be the only part of the thyroid gland which absorbs iodine. Since iodine is a chemical requisite of the thyroid hormone, the adenoma is the only part forming hormone and must therefore be responsible for the excess. The uninvolved tissue which collects no iodine and inactivates no pituitary stimulating hormone is apparently at physiologic rest and is anatomically atrophied. Thus the term adenoma used to denote a benign neoplasm has been given a physiologic as well as anatomic meaning. Strictly neoplasia means an abnormal growth of tissue which takes place without regard to the laws governing the normal portions of the gland. In these cases the excessive function has been assumed by the adenoma indicating a disordered secretory activity in addition to the pathologic cell growth. In contrast the uninvolved tissue obeys physiologic laws and rests in the presence of an excess of the hormone; its disorder of function is secondary and the tissue is not in itself diseased.

The single adenoma is a rare cause of hyperthyroidism. It is best considered as a pathologic type at the extreme from the diffuse hyperplasia which is the common type associated with hyperfunction. The disease types in the thyroid and parathyroid glands are thus reversed.¹ As with hyperparathyroidism due to adenoma, hyperthyroidism may also be associated with more than one adenoma. We have encountered 2 cases with two adenomas each. That the neoplasms or adenomas were the cause of the hyperfunction is indicated by the accompanying atrophy of the uninvolved tissue comparable to that found in the cases with the single hyperfunctioning adenomas described in this paper. Doubtless cases will be found in which there are multiple adenomas.

NOT 8 cases of hyperparathyroidism proved by operation: 1 the Massachusetts General Hospital, 72 have had the localized form of a toxic disorder. 1/20 one gland only has shown an anatomic abnormality and in some of these not even the whole gland has been involved in the disease process; a small rim of uninvolved parathyroid tissue has surrounded the diseased tissue. In 5 of the 75 cases, two glands, rather than only one, have shown changes; the other two glands of each patient were not involved. Because of the localized nature of the disease in these 75 cases the lesion has been considered neoplastic and has been called an adenoma. In 7 of the 8 cases of hyperparathyroidism the disease process has involved all of the tissue of all 4 of the parathyroid glands and has been termed hyperplasia by some and hypertrophy by others. That the disease process is considered different from that of the localized neoplasia or adenoma is strengthened by the fact that the cell type and arrangement of the hyperplastic glands is clearly distinguishable from those of the cells found in the adenomas.

all hyperfunctioning. The differentiation of the lumps as true neoplasms will depend upon the demonstration of physiologic rest of the uninvolved tissue in contrast to hyperfunctioning paraneoplastic tissue of nodular goiter with hyperthyroidism (12). Indeed henceforth distinction between lumpy diffuse goiter with hyperthyroidism and true neoplastic or adenomatous goiter must be made by simultaneous scrutiny of all the nodules and the uninvolved or paraneoplastic tissue.

The observation that the disease process in the thyroid is localized to one part of the gland suggests that the origin of the disease is different from that of the diffuse hyperplasia type in which all of the tissue is acting beyond normal physiologic control. Our studies give no clue as to the nature of the initiating process. It is of interest that the clinical disease produced by the hyperfunctioning single adenoma did not differ significantly from Graves disease with the diffuse goiter. There is a suggestion that eye signs, particularly exophthalmos, were less frequently encountered but the number of cases is too small to be sure that this difference was not due to the age of the patients. That the function of the majority of the adenomas was not affected by iodine is certain.

Of significance to the surgeon is the finding that the uninvolved tissue obeys physiologically the law of supply and demand as far as function is concerned and is therefore not diseased. Nothing is to be gained by excising it. Indeed it would be better to leave all of it behind, the better to insure more prompt and complete return of function. If the surgeon is familiar with tissue atrophied by disuse, little difficulty will be encountered in recognizing it.

We have not had an opportunity to test the efficacy of radioactive iodine in therapeutic doses in reducing the secretory activity of a hyperfunctioning adenoma. Presumably it should prove effective though the failure of roentgen irradiation in the 2 cases in which this latter agent was employed suggests that larger doses of radioactive iodine might be needed than in Graves disease with diffuse hyperplastic goiter. It is not surprising that thiouracil was effective in lowering the metabolic rate in the patient in whom this drug was

tried. From a chemical point of view thiouracil should block formation of the thyroid hormone by any cell neoplastic, as well as hyperplastic and normal (9). The ultimate fate of the adenomatous cell after both radioactive iodine and thiouracil therapy remains to be established.

SUMMARY

The single adenoma of the thyroid gland causing hyperthyroidism is established as an entity. It is the rare type of pathologic anatomy found in patients with thyrotoxicosis. 10 cases have been encountered in the Thyroid Clinic at the Massachusetts General Hospital in the last 10 years. Proof of its existence in a patient depends upon the absence of other diseased thyroid tissue, the presence of gross anatomic atrophy and of physiologic inactivity of the uninvolved thyroid tissue and relief of the excessive function upon its removal.

The atrophy of the uninvolved thyroid tissue can be suspected on physical examination but should always be recognized at operation and undue resection of it avoided.

The physiologic activity of the adenoma and uninvolved thyroid gland has been compared by the ability of explanted thyroid tissue to inactivate thyroid stimulating hormone and by the avidity of the thyroid for tracer doses of radioactive iodine. Both tests have shown activity of the adenoma comparable to that found in the hyperplasia of the common type of thyrotoxicosis and absence of function of the uninvolved tissue.

The absorption of tracer doses of radioactive iodine by single adenomas not associated with hyperthyroidism suggests that the secretory activity of adenomatous tissue varies over a wide range and that the presence of thyrotoxicosis in a patient depends upon the degree of activity and size of the adenoma. The activity of the accompanying uninvolved tissue varies inversely and is depressed when that of the adenomatous approaches an excessive amount.

The relative effectiveness of thiouracil and radioactive iodine compared with surgery in relieving the hyperfunction associated with this pathologic type, and the eventual fate of the localized neoplastic process when these two drugs are employed has not been established.

ADDENDUM.—Since this manuscript was submitted for publication the distribution of radioactive iodine in the adenoma compared with that in the atrophic uninvolved tissue has been observed in 2 additional patients with thyrotoxicosis due to a hyperfunctioning single adenoma. The first patient, a girl of 7 years, had a mild degree of thyrotoxicosis; the adenoma contained 8.1 per cent per gram of the radioactive iodine given, the uninvolved thyroid tissues 0.030 per cent per gram and a lymph node .04 per cent per gram. The second patient, a woman of 35 years, had a moderate but crippling degree of thyrotoxicosis; the adenoma contained .88 per cent per gram of the radioactive iodine; the uninvolved tissues .57 per cent per gram. Removal of the single adenoma and resection of a gram only of the uninvolved tissue for analysis, resulted in relief of the thyrotoxicosis in both cases.

RESECTION OF THE COMMON HEPATIC DUCT FOR PAPILLARY ADENOCARCINOMA

J PEYTON BARNES M D F.A.C.S and L LYNN ZARR M D Houston Texas

A PRIMARY carcinoma of the extra hepatic bile ducts especially if those of the ampulla of Vater are excluded is an extremely rare finding. Pathologically there are two types the nodular and the papillary and of these the latter is most infrequent comprising only about 10 per cent of the total. All writers agree that papillomatous growths in the bile ducts will obstruct the lumen before penetrating the wall of the duct in brief they probably remain as a local lesion long enough to produce definite symptoms before metastases take place. Marshall found 4 papillary carcinomas of the extra hepatic ducts in a series of 49 carcinomas of these structures and stated that most papillary growths in this region would prove malignant on section.

Males (60%) more often than females are affected with carcinoma of the bile ducts but females are more often affected with carcinoma of the gall bladder (80%) (1). The average age of individuals with bile duct carcinoma is 55.5 years. Carcinoma of the gall bladder is said to be four times as common as carcinoma of the bile ducts.

In the series presented in Table I (1) if one includes under one heading all the tumors arising from the common bile duct including the ampulla then the common bile duct is the most frequent site with 210 next is the junction of the three ducts—cystic, common and hepatic duct with 124. The hepatic ducts right left and common present the next most frequent site with 87 and the cystic duct is the least frequent site. We were able to find only 21 cases in which the common hepatic duct alone was involved, 19 reported by Rolleston and McNee and 2 by Marshall but this figure may not be accurate.

Symptoms. Jaundice is present in 100 per cent of cases. Complete biliary obstruction is present in over 90 per cent. The onset is acute in almost 90 per cent. Loss of weight and

strength also occurs in nearly all if not all patients. Pain is present in about 52 per cent. Chills, elevation of temperature vomiting diarrhea and pruritis are common. Ordinarily no mass is palpable in region of primary tumor the liver is enlarged in 68 per cent and the gall bladder in 26 per cent, and about 50 per cent have ascites.

CASE REPORT

Mr C S C white aged 73 years entered Heights Hospital February 2 1946. His chief complaints were marked jaundice widespread itching loss of 20 to 30 pounds in weight persistent diarrhea. His present illness began about 8 weeks before admission with indigestion and a mild burning and huddling in his stomach. After a week of this he began to develop a yellow color and his stools became rather light in appearance. The jaundice was first noted December 20 1945 and gradually became more pronounced. At no time was there any definite pain in the abdomen. There was no fever no chills no nausea or vomiting. Three weeks after jaundice appeared itching was rather marked. Until admission to hospital he had a rather continuous diarrhea and lost considerable weight probably 20 to 30 pounds but felt hungry and ate all types of food during the present illness.

He had usual childhood diseases and typhoid at 27 years. He had had an appendectomy 10 years before and 5 years before had had 18 skin lesions stated to be skin cancers removed from back of neck and right ear. None of these had recurred.

His father died at 82 years cause unknown. Mother died at 69 of hypertension. One brother died at 58 of heart attack and two sisters ages unknown, living one sister with tuberculosis. No history of cancer or tuberculosis otherwise in family.

Physical examination revealed a thin emaciated white man with marked icteric tint to skin and sclera, many skin abrasions as result of scratching. Patient was mentally alert, not toxic, very cooperative in all respects. His blood pressure was 140/90 the heart action was a little irregular there was no cardiac enlargement but there was a rather loud systolic murmur at the apex. The lungs were clear. The abdomen was markedly scaphoid and the liver was enlarged about three fingersbreadth below the costal margin. The spleen was not palpable. No other masses other than the enlarged liver were noted. Rectal examination was essentially negative.

Fig. 1. The upper oblique incision (Singleton)

Fig. 2. Greatly enlarged liver and distended gall bladder

no nodules on rectal shelf. The temperature was 98 degrees pulse good volume slightly irregular.

Laboratory examination on February 4, 1946 showed urine—dark amber clear alkaline specific gravity 1022 albumen 0 sugar 0 blood 0 epithelium cells rare casts granular rare bile present. Blood—red blood count 4,040,000, hemoglobin 80 per cent Sahli white blood count 5,800 polymorphonuclears, 58 lymphocytes, 40 juveniles 2 icterus index, 100.

He was seen in consultation February 3, 1946 by Dr. E. K. Doak, whose impression was that it was a malignant condition causing obstruction of the biliary tract and advised a gastrointestinal series. This was done by Dr. B. T. Vanant and was essentially negative except for a large number of diverticula in the lower sigmoid. His report is as follows: "February 4, 1946 G. I. Series. Fluoroscopically the upper half of the stomach is a mere tube with greatly thickened longitudinal mucosal folds. The material passes immediately into the duodenum and on into the small intestines."

At the end of four hours stomach is practically empty. Residue shows an extremely ragged lake-like residue with all the opaque material in the ileum and first portion of duodenum.

Six hour plate terminal ileum and the first portion of ascending colon contains all material.

Twenty four hour plate colon is empty except for small amount in the transverse colon. A small retention pocket in the caecum, a slightly larger retention pocket in the splenic flexure with only a moderate amount in the sigmoid.

In the six hour plate we notice in the right lower quadrant, a very large number of shot-like pockets, evidently in the wall of the small intestine and at the twenty four hour plate, the lower sigmoid shows a large number of diverticulae.

"The case is apparently one of generalized hypermotility and general spasticity. Unable to find any definite anatomical lesion."

Would suggest the possibility of a very mild avitaminosis of the pellagra type.

We believed that it was most likely a case of carcinoma of the head of the pancreas and so advised our patient. It was decided that the abdomen should be explored in the hope that his condition could be improved, and he was therefore prepared for surgery. He was given daily doses of vitamins A and D with bile salts, large amounts of vitamins A and B complex, also 2 cubic centimeters of crude

TABLE I.—LOCATION OF EXTRABILIARY DUCT TUMORS IN 484 PATIENTS

Fig 3 Tumor shown in common hepatic duct extending almost to bifurcation of duct.

liver intramuscularly. He was also given digitals for 3 days before operation plus two transfusions of 500 cubic centimeters each. Operation was done February 15, 1946. Pentothal was used for induction.

An upper oblique incision was used (Fig 1) transecting the right rectus muscle. When the abdomen was opened the liver was seen to be greatly enlarged with rounded edges, greenish black in color and the gall bladder to be enormously distended (Fig 2) at least four or five times normal size but of a rather normal color and thickness. We then examined the pancreas, which we fully expected to find hard and enlarged but to our amazement it felt entirely normal. This fact was so astonishing that we could hardly believe it and we incised the peritoneum lateral to the duodenum mobilized the duodenum and carefully explored the entire retroduodenal portion of the common duct and found it, as well as the adjacent pancreas entirely normal in all respects. Then a small oblong mass about the size of a large pecan (Fig 3) was noted up toward the fissure of the liver. We decided that it must be a stone or tumor in the common hepatic duct. A small nick was made in it and confirmed the fact that it was the duct and that a tumor was present therein.

No nodules could be felt in the liver or adjacent structures, and it was decided to resect

Fig 4. Aspiration of distended gall bladder: black bile obtained.

the tumor bearing section of the duct. To facilitate exposure the gall bladder was aspirated through the fundus (Fig 4) and a large amount of black bile was removed. Then the duct was cut across transversely as far above the tumor as possible; this was right against the liver (Fig 5). It was then cut through below the tumor and the distal end closed over with a continuous stitch of No. 6 chromic plus an ordinary tie below this suture line (Fig 6). A lymph node adjacent to the tumor was also removed for examination.

Fig 5. Common hepatic duct sectioned near proximal end. Distal line of section indicated by dotted line.

Fig. 1 The upper abdominal incision (Singleton)

Fig. 2 Greatly enlarged liver and distended gall bladder

no nodules on rectal shelf. The temperature was 98 degrees pulse good volume slightly irregular.

Laboratory examination on February 4, 1946 showed urine—dark amber clear alkaline specific gravity 1.022 albumen 0 sugar 0 blood 0 epithelium cells rare cast granular rare bile present. He was in consultation February 3, 1946 by Dr. E. K. Doak whose impression was that it was a malignant condition causing obstruction of the biliary tract and I advised a gastrointestinal series. This was done by Dr. B. T. Vanzant and I was essentially negative except for a large number of diverticula in the lower sigmoid. His report is as follows: February 4, 1946 G. I. Series. Fluoroscopically the upper half of the stomach is a mere tube with greatly thickened longitudinal mucosal folds. The material passes immediately into the duodenum and on into the small intestines.

At the end of four hours at which is practically empty. Residue was an extremely ragged lake-like residue with all the opaque material in the rectum and first portion of duodenum.

Six hour plate terminal ileum and the first portion of ascending colon contains all material.

Twenty-four hour plate colon is empty except for small amount in the transverse colon. A small retention pocket in the caecum, a slightly larger retention pocket in the splenic flexure with small moderate amount in the sigmoid.

In the six hour plate we notice in the right lower quadrant a very large number of shoe-like pockets, evidently in the wall of the small intestine and in the twenty-four hour plate the lower sigmoid shows large number of diverticulae.

The case is apparently one of generalized hypomotility and general spasticity. Unable to detect any definite anatomical lesion.

Would suggest the possibility of a very marked avitaminosis of the pellagra type.

We believed that it was most likely a case of carcinoma of the head of the pancreas and so advised our patient. It was decided that the abdomen should be explored in the hope that his condition could be improved and he was therefore prepared for surgery. He was given daily doses of vitamins E with bile salts, large amounts of vitamins A and D and B complex, also 2 cubic centimeters of crude

TABLE 1—LOCATION OF EXTRABILIARY DUCT TUMORS IN 484 PATIENTS

Fig 3 Tumor shown in common hepatic duct extending almost to bifurcation of duct.

liver intramuscularly. He was also given digitalis for 3 days before operation plus two transfusions of 500 cubic centimeters each. Operation was done February 15, 1946. Pentothal was used for induction.

An upper oblique incision was used (Fig 1) transecting the right rectus muscle. When the abdomen was opened the liver was seen to be greatly enlarged with rounded edges, greenish black in color and the gall bladder to be enormously distended (Fig 2) at least four or five times normal size but of a rather normal color and thickness. We then examined the pancreas which we fully expected to find hard and enlarged but to our amazement it felt entirely normal. This fact was so astonishing that we could hardly believe it and we incised the peritoneum lateral to the duodenum mobilized the duodenum and carefully explored the entire retroduodenal portion of the common duct and found it, as well as the adjacent pancreas entirely normal in all respects. Then a small oblong mass about the size of a large pecan (Fig 3) was noted up toward the fissure of the liver. We decided that it must be a stone or tumor in the common hepatic duct. A small nick was made in it and confirmed the fact that it was the duct and that a tumor was present therein.

No nodules could be felt in the liver or adjacent structures, and it was decided to resect

Fig 4 Aspiration of distended gall bladder black bile obtained.

the tumor bearing section of the duct. To facilitate exposure, the gall bladder was aspirated through the fundus (Fig 4) and a large amount of black bile was removed. Then the duct was cut across transversely as far above the tumor as possible this was right against the liver (Fig 5). It was then cut through below the tumor and the distal end closed over with a continuous stitch of No. 0 chromic plus an ordinary tie below this suture line (Fig 6). A lymph node adjacent to the tumor was also removed for examination.

Fig 5 Common hepatic duct sectioned near proximal end. Distal line of section indicated by dotted line.

Fig. 6. Distal end of hepatic duct closed, proximal end open. Gall bladder sectioned through ampulla, distal edge not crushed.

Fig. 7. Probing cystic duct in order to determine patency should be carried out before removal of the gall bladder.

The problem of bridging the gap between the cut ends of the common hepatic duct was managed by using the cystic duct and the ampulla of the gall bladder to provide a mucous membrane lined tube and a tube already accustomed to handling biliary drainage which permitted little chance for later stricture development.

A forceps was applied across the ampulla of the gall bladder and it was cut across proximal to this (Fig 6). The edge not crushed by the forceps was used for the anastomosis. A probe was then passed through the ampulla down the cystic duct and the common duct into the duodenum doubly to assure the patency of the entire tract (Fig 7). This flanged out ampulla (which was assurance against later stricture formation) was then sutured to the open end of the common hepatic duct *everting* rather than inverting the edges (Fig 8a), a further step in preventing stricture formation with chromic on atraumatic needles. A small catheter, size 12 French, was placed so that its bell end opened into the proximal end of the common hepatic duct, and it was brought out through a tiny incision in the ampullary portion (Fig 8a). The remainder of the gall bladder was then removed and bed sutured over (Fig 8b).

Three Penrose drains were placed and brought out through the main incision. The catheter was brought through the main incision also but about an inch away from the drains.

The tumor filled the entire section of duct except for a very small space through which a small probe could be passed. The growth of the tumor was producing a very marked intraluminal pressure as it bulged outward.

The tumor was examined by Dr. A. H. Boies, whose report is as follows:

An irregular mass from the hepatic duct measuring 3.5 by 2 cms. The color is brownish and the tissue is moderately firm with softer areas in the center. A lymph gland which measures 7 by 4 by 5 mm is fairly regular in shape and is rather soft. Microscopically sections were made from both extremes. Some of the sections show rather large gland acini lined by single layers of cuboidal cells filled with mucinous material (Figs. 9 and 10). Other sections show atypical gland acini that are lined by hyperplastic cells that are irregular in size and shape with mitotic figures that are atypical. The arrangement is quite frequently papillomatous (Figs. 11 and 12). The wall is not demarcated other than a connective tissue band between the glandular tissue. Sections from the lymph node show no evidence of metastasis. Diagnosis: papillary adenocarcinoma, grade II.

The gall bladder aside from its marked distention, was normal. He made a good recovery and the

Fig. 8. a, left, Anastomosis of ampulla to proximal end of common hepatic duct. Note eversion of edges, catheter drain. b Completed operation.

only complication was a failure of the skin edges to unite. The deeper layers all held; he had no hernia but a secondary closure of the skin edges was necessary. Highest postoperative temperature was 99.8

passed on into the duodenum (Fig. 13). At this time his urine still contained bile and the stools were negative for bile. Report of the x-ray examination for March 5, 1946 was

"Beautiful filling of all the hepatic ducts. Common duct is open and material flows freely into duodenum."

On March 16 another injection was done demonstrating the same situation. X-ray report for March 16, 1946 (Fig. 14) was

"Very excellent injection of the biliary tree. The material flows into the duodenum."

He continued to improve; the external biliary drainage became much less 36 hours after the catheter was removed on March 18 and on March 22 he was allowed up in a wheelchair. His stools were beginning to have a more normal color; his appetite was very good and he felt himself gaining strength every day. By March 25 there was almost no drainage and he was allowed to go home.

This case has unusual features

1. With marked loss of weight and strength, he still had a good blood count.

2. His appetite was never bad even from the beginning.

Date	Icterus index	Stools (bile) Albumen globulin	Urine (bile)

3 We wonder if any connection exists between the numerous skin cancers removed 5 years before. Once before one of us (J P B) saw an elderly man develop primary carcinoma of the liver 10 years after having had a basal cell carcinoma of the face removed with radium.

We believe that the obstruction was complete but that at times a little bile was forced

through the narrow tract by pressure from the liver otherwise the bile in the gall bladder would have been "white bile" instead of the black.

If no bile at all had reached the intestine he would have had marked anorexia, but this was not the case.

We are unable to explain the enormously distended gall bladder. According to Cow

Fig. 11. Papillomatous arrangement, typical gland acini. Low power

Fig. 14. Note injection of cystic and common bile ducts. Media passes into duodenum.

Voisier's law (extrinsic pressure on the ducts (and usually pressure exerted at a point distal to the junction of cystic and hepatic ducts) produces a distended gall bladder. Here the pressure was intrinsic and was at a point well proximal to the junction of cystic and hepatic duct. It was evident that bile was getting by in tiny amounts and being stored up in the gall bladder but the gall bladder was not contracting and emptying itself through the sphincter of Oddi very well. Perhaps the abnormal pressure in the hepatic duct in some way interfered with the reciprocal autonomic regulation of the gall bladder sphincter of Oddi mechanism.

The cystic duct here was quite small but a 3 millimeter dilator could be passed through it and we depended on the inherent ability of the duct as a mucous membrane lined tube to dilate sufficiently to carry the total biliary stream. The correctness of this assumption was demonstrated clinically when at removal of the catheter the external drainage promptly ceased, the urine cleared and the stools regained their normal color. This characteristic ability of a mucous membrane lined channel to dilate and thus carry a heavier load than nature originally intended should always be remembered in dealing with similar problems.

The use of the ampulla of the gall bladder is noteworthy. Every end-to-end anastomosis, especially when the ends are inverted as in intestinal work, has a certain amount of narrowing due to slight septum formation by the inverted portion plus a later contraction of the circular line of union. Therefore we used a section of the gall bladder with at least twice the cross section diameter of the stump of the duct to which it would be joined. The edges were everted and thus no septum or spur whatever was formed. So far as we know this procedure has not been previously reported.

On July 20, 1946 a follow up revealed our patient in good condition, his wound well healed, no jaundice and a good appetite and he had gained 18 pounds since leaving the hospital March 25, 1946.

In reviewing this case attention is called to an alternate method that might be used in a similar case. The method presented depends upon a patent cystic duct. Most cystic ducts are patent, yet the possibility of a closed duct must be remembered. Where a diagnosis of hepatic duct tumor has been made at operation and the gall bladder present and healthy the following method of attack is suggested.

Aspirate the gall bladder preferably near or at the fundus.

Probe the cystic duct either through the aspiration opening in the gall bladder or through a small opening in the ampullary region and if patent the method already presented may be used if desired, but if for any reason it is not applicable the following method may be employed

Resect the hepatic duct tumor but make every effort not to damage either the cystic or hepatic artery

Do not close the distal end of severed hepatic duct

Beginning at the fundus, dissect the gall bladder away from its bed protecting the cystic artery at the base of the flap

Anastomose the fundus of gall bladder to proximal end of hepatic duct

Implant distal end of hepatic duct into side of gall bladder which will probably be a little

above the ampullary region. If the gall bladder should be half as large as in the case presented no trouble will be experienced.

Put catheter or soft T tube in gall bladder

SUMMARY

A case of papillary adenocarcinoma of the common hepatic duct, with successful resection has been presented. A method of wiring the ampulla of the gall bladder and cystic duct as a substitute for the common hepatic duct has been demonstrated

The experience that iliac bone is more rapidly incorporated into the host bone than cortical bone when used as graft material as reported in the author's initial communication has been sustained. This fact has not only been interpreted on the basis of the roentgenographic features of graft incorporation but from the gross and microscopical features of graft specimens removed at the time of reoperation in 6 patients. These observations have served to sustain the concept that cancellous bone by the nature of its architecture encourages more rapid invasion and replacement by new bone than does cortical bone. This has held true not only in the instance of small chip and sliver grafts which have been used to fill in bone cavities and to reinforce cortical grafts but in our cases where the cancellous grafts have been massive. The technique of exposure of the iliac wing by liberal stripping subperiosteally of soft tissues

from both the external and internal aspect has permitted the removal of massive grafts which are easily shaped with the electric saw to bridge ununited fractures and to fill bone defects (Fig. 1 a and b). This is further facilitated by the control of bleeding with the electric cautery. By the use of the electric knife and by the removal of the graft with the longitudinal attachment of the Lock saw.

In discussing graft material the authors are fully aware that no bone graft specimen is wholly cancellous or cortical bone. The massive iliac graft while it is mainly cancellous in structure has an inner and outer table of cortical bone which in effect lend to the stability of this type of graft while a cortical graft from the femur or tibia may have a layer of cancellous bone on its deep surface and a variable amount at its end depending on how much of the metaphysis of the donor area has been removed.

Those who have used cortical grafts especially to bridge gaps, know that a critical

period exists after the third month at which time the center of the graft may begin to resorb and may disappear or be the site of a fracture. In this type of graft this phase of resorption is easily detected on roentgenograms the cortical graft appears denser and whiter than the adjacent host bone. The same phenomenon may occur with massive iliac grafts although this is harder to detect on roentgenograms where the cancellous graft fails to stand out in contrast to the surrounding bone. In 3 cases 1 with a nonunion of both bones of the midforearm another of the surgical neck of the humerus and the third involving the upper third of the femur dissolution of the central portion of the massive iliac graft appeared between the third and fourth postoperative month with recurrence of nonunion while in a fourth case a nonunion of the forearm recurred after the use of an iliac graft with a plate which had bridged the fracture inadequately the graft resorbing in its center in like manner. In other words although cancellous bone is more rapidly incorporated into host bone when used as graft material, its central portion where the process of creeping substitution and the replacement of new bone by mature bone is last manifest represents a site of structural weakness which requires prolonged and rigid support and protection. This is especially true where the graft is bridging a gap and is surrounded in this region solely by soft tissues. Rigid fixation cannot be obtained by plaster of Paris alone no matter how accurately applied, and it is best secured by the use of a metal plate. Such additional plate fixation is absolutely necessary in the grafting of single long bones as the femur and humerus, and particularly in their upper and middle thirds where the stress of the lever action of the extremity is most vicious and in the forearm and leg when both long bones are ununited. In the forearm and leg where one of the long bones is intact, the splintage afforded by the intact component will suffice with the usual method of fixation of the graft and a plate need not be utilized. Recurrence of nonunion has occurred in this group of patients, excluding those failures incidental to postoperative infection as a result of failure to recognize two essential mechanical

Fig. 3 Patient sustained a compound fracture of the right femur in a motorcycle accident. Reconstruction of a nonunion with gap-defect was performed by means of a massive cortical graft from the left tibia, which was affixed as an onlay to the proximal femoral fragment with three stainless steel screws after its distal end had been driven into and well impacted within the substance of the short atrophic distal fragment. The use of a metallic plate was mechanically impossible in this subject. The anteroposterior roentgenographic view made 3 weeks postoperatively and just prior to his transfer to another military hospital, is illustrated. The limb was protected in balanced suspension with skeletal traction through the upper end of the tibia at the time that this examination was made.

principles early in this study 1c the need for metallic plate fixation in certain instances as defined above and the need for rigid fixation by plates of adequate length.

On the other hand iliac bone when it includes one and especially both tables, has sufficient stability for use alone and without plate fixation as in the treatment of ununited fractures of a single forearm bone or of the tibia in the presence of an intact fibula, and when it is fashioned from the iliac crest and includes three cortical surfaces—the crest and both tables—it is as rigid as a segment of cortical bone of similar dimensions.

Cortical bone must be used in selected cases

a. Where the graft is necessary to bridge a considerable gap as in the femur and must measure in excess of 5 inches it is obligatory that cortical bone be used. The osteogenic properties of such massive cortical grafts will

Fig. 3. a and b. Patient sustained severe compound comminuted fractures of the right femur as the result of enemy shell fire. An onlay iliac graft, fixed with stainless steel screws, was employed to bridge the 3 inch (7.5 cm.) defect and the internal was packed with shivers of iliac bone. The wound healed *per primam* but despite adequate protection of the extremity in balanced suspension and skeletal traction, the center of the graft proceeded to resorb with recurrence of nonunion 6 months postoperatively. A second graft, obtained from the left tibia, was applied and rigid fixation secured by the application of a stainless steel plate. a, left, is an anteroposterior roentgenogram of the femur just prior to the second grafting and, b, right, is an anteroposterior view made 6 weeks following this operation. The limb was protected in balanced suspension with skeletal traction through the upper end of the tibia at the time this report was completed.

be enhanced by the additional use of shivers of cancellous bone removed from the ilium. This has been the experience in 3 patients with ununited fractures of the femur and with massive defects. In one of these dual tibial grafts were applied and transfixed to each other and to the atrophic ends of the femoral fragments and further fixation was obtained by a long metal plate. In the second case the massive cortical graft removed from the tibia was transfixed to the proximal fragment with three screws and its distal end was driven into the spongy substance of the short distal fragment for a distance of about 2 inches (Fig. 2). In the third case a massive iliac graft resorbed in its central portion with recurrence of nonunion (Fig. 3a). At operation the defect was bridged and rigidly im-

mobilized with a metallic plate and a massive cortical graft was applied (Fig. 3b).

In a fourth instance where a gap of 5 inches existed in the upper end of the humerus with loss of the humeral head and entire glenoid, the shaft of one fibula was used between the remains of the scapula and the humeral shaft, being driven into the humeral fragment distally and transfixed at its proximal forked extremity with one screw. In this case resorption occurred in the center of the graft with a pathologic fracture even though the area appeared adequately protected in plaster of Paris. At the time of regrafting the viable fibular fragments were found to be firmly incorporated into the host bone and the pathologic fracture was bridged by a tibial graft held with two screws above and two below the

fracture site. Union of the pathologic fracture has occurred and the tibial graft is becoming incorporated into the substance of the original fibular graft (Fig 4).

b. Cortical bone must be used where a rigid piece of bone which is perfectly straight is required as graft material. For instance, in 1 patient two cortical grafts were introduced across an ununited fracture of the neck of the femur with viable head one above and the other below an accurately placed Smith Peterson nail. Since the grafts were applied through the greater trochanter channels having been drilled accurately under roentgenographic control it was essential to use an absolutely straight graft of rigid nature which would tolerate introduction with a mallet, and cortical bone was felt to be most suitable. The writers have had the same experience with the use of cortical grafts in the Brittain type of hip fusion although this type of case is not included in this report.

2. *The specific place for plate fixation in combination with iliac grafts fixation by multiple screws in oblique fractures.* The specific purpose of a metallic plate is to give rigid fixation to the fracture and to protect the graft throughout its period of incorporation. When the iliac graft is applied across the fracture site or defect and is transfixed with screws through graft and both cortices of the host bone and at right angles to the plate and its screws added fixation is insured.

The duration of the period of external fixation varies with each case. Much depends upon the degree of stability of the fracture as determined preoperatively the method of internal fixation employed at the time of operation, and the size and nature of the defect for the greater the defect the longer the period required for complete revitalization of the graft and the greater the danger of its resorption or fracture. The degree and length of protection will also depend upon the site of the defect. The demands for protection are greatest for a weight bearing bone (femur or tibia) and for a single bone as the femur or humerus particularly in their middle and upper thirds or

Fig 4. Enormous defect in the rigid humerus following a compound comminuted fracture incurred in battle with loss of the proximal half of the humerus and the entire shoulder joint. At the first operation a fibula graft was inserted between the acapular blade and the distal humeral fragment, but the center of this graft, despite protection of the extremity in plaster of Paris, resorbed in its center with the appearance of a pathologic fracture 6 months post-operatively. The illustration shows the roentgenographic appearance 3 months following the second operation at which time the fibular fragments were reduced and immobilized by an oblique tibial graft. The fibula now appears to be well united and the tibial graft is undergoing incorporation into the adjacent bone. The extremity was protected in a plaster-of Paris shoulder spica at the time this report was completed.

for double bone involvement in the forearm and leg. An intact radius ulna, or fibula offers considerable protection to a fracture of the adjacent bone.

In the instance of ununited fractures of the femur plate-graft fixation has been rigid enough to warrant the elimination of post-operative plaster-of Paris fixation and the extremity has been protected by skeletal traction in balanced suspension. Such patients have been up in an ischial weight bearing brace 4 months postoperatively with full weight bearing by the 6th month and brace support has been discarded between the 9th and 12th month postoperatively (Fig 5 a and b Fig 6 a and b). Patients with ununited fractures of the tibia treated by the graft plate technique have often borne weight in a walking cast between the 3rd and 4th postoperative month and this has been followed by brace protection for 6 months or if there has

This may be varied in the instance of extremely porous bone where the graft is applied cross the fracture at directly opposite the plate, permitting a more secure bony purchase for the screws fixing the plate.

Fig. 5, a and b. Simple fracture of the left femur which was treated by open reduction and plate fixation 6 weeks after injury by a falling log. Delayed union with an interval gap between the fragment ends and with little callus formation was evident 6 months later. An iliac bone graft was applied and the metallic plate left *in situ*. a and b, Anteroposterior and lateral roentgenograms of the femur made one year postoperatively. The medullary canal is reforming, there is thorough incorporation of the bone graft and union is solid. Note how the superficial portion of the massive graft has resorbed, as evidenced by some protrusion of the screws and it is for this reason that the operative technique has been modified to include counter sinking of the main graft. Brace support was eliminated in this case 9 months postoperatively.

been much bony defect, for 9 months. Fractures of the upper extremity have been mobilized at the end of 3 months being protected in an abduction cast or brace when the fracture involved the upper third of the humerus or by a bivalved hanging cast for fractures distal to this region.

It is the experience of the writers that the use of a plate in addition to the bone graft is absolutely essential in the surgery of ununited fractures of solitary long bones such as the femur and humerus particularly in their upper thirds where the lever action of the extremity is most vicious. Nonunions have recurred in one case in the surgical neck of the humerus and in another in the upper third of the femur following bone grafts with simple screw fixation even though the humerus case appeared adequately protected in a plaster-of-Paris shoulder spica and the femur was still supported in traction-suspension. Even in the instance of massive defects where the union is afforded by a narrow osseous bridge and where

Fig. 6, a and b. Compound comminuted fracture of the right femur incurred in battle with resultant sepsis which was treated by the iliac graft metallic plate open 7½ months after the initial injury and 6 months after cessation of all drainage. a and b, Anteroposterior and lateral roentgenograms made one year postoperatively. The graft is completely incorporated into the host bone, there is solid union of the fracture, and the medullary canal is reforming. Brace discarded in this case 9 months postoperatively.

this lesion exists in the upper third of the humerus or femur the authors advocate that a metallic plate be employed in addition to the replacement graft (Fig. 7 a, b and c). In the forearm where both bones are united, plating of the ulna in addition to grafts of both radius and ulna is recommended, while in the leg when both tibia and fibula are united the plate-graft technique is recommended for the tibia. As noted before, in the forearm if the radius or ulna is intact and in the leg if the fibula is intact, sufficient stability is afforded and a plate need not be used (Figs. 8, 9).

The greatest problem has been to apply the plate in such a manner as to secure maximum rigidity and for this reason since the shape of the fracture gap and the fragment ends vary widely the site and manner of application of the plate must be varied to conform to the mechanical requirements in each case. It is essential to have a plate that is long enough and to have at least two and preferably three screws fixed firmly above and below the fracture level. In the presence of long bone defects a plate longer than that usually employed for

Fig. 7 a, b, and c. This subject incurred a compound comminuted fracture in the upper third of the left femur in battle. Seven months later he presented a large defect at the fracture site with a narrow bony bridge across this defect. Strengthening of the strut by an iliac graft and filling of the defect with shivers of iliac bone was performed; the graft being held securely by two screws above and two screws below, as shown in a, left. Four months later, although the extremity was still protected in balanced suspension and without any history of an injury, a check roentgenogram (b, center) demonstrated increased lateral bowing of the femoral fragments. At reoperation, motion at the fracture site and at the proximal end of the graft was demonstrable. A metallic plate was applied laterally after correction of some of the lateral bowing and the iliac graft was applied to bridge the defect more securely (c, right). Anteroposterior roentgenogram made 2 weeks following the plate-graft operation. The limb was supported in balanced suspension with pin traction through the distal end of the femur at the time this report was completed.

that particular long bone will have to be used. For this reason the longest standard type metal plate utilized for the internal fixation of fractures of the femur is inadequate in the treatment of considerable gaps in that long bone. The authors have had to improvise and fashion plates as long as 9 inches in length in order to bridge certain femoral defects and yet insure adequate proximal and distal screw fixation, and this material has been usually derived from the long arm of the longest Moore type plate. If the technique herein reported is acceptable it becomes apparent that plates up to at least 10 inches (25 cm.) in length must be manufactured of stainless steel or vitallium, and the authors have called attention to this need. In a nonunion of the subtrochanteric region of the femur the Blount or Moore plate has served effectively for application of the graft plate technique in this region.

Another method of internal fixation has been employed which is restricted to the

oblique type of ununited fracture and which has permitted the elimination of a plate in such cases at the time of application of the bone graft. The fracture is transfixed after freshening its surfaces and insuring accurate contact by two or three screws, and then the graft is applied at right angles in a prepared bed across the fracture and is held by two screws above and two below this site. This technique has been employed in the tibia and ulna, and in the instance of the tibia the graft has been applied wherever possible on the fibular side and in the ulna on its radial side.

3. *Modifications and variations in the technique of the combined graft plate method and of bone grafting without plate fixation.* While the authors recommend the use of plates and screws as an essential feature of their grafting technique, they are fully aware of the undesirable features of metallic internal fixation. There is no question that once postoperative infection has occurred (and the potentiality

Fig. 8. Compound comminuted fracture of the left radius, incurred in battle, with resultant nonunion and a gap-defect of 2 inches. At operation 6 months following the cessation of all drainage, an iliac graft, shaped to fit the oblique ends of the radial fragments, was interposed and affixed by screws proximally and distally. The ulna was intact but its distal end was resected to permit more accurate repositioning of the fragments of the radius and to correct the radial deviation of the hand and wrist.

The illustrations of the anteroposterior and lateral roentgenograms made 3 months postoperatively show good incorporation of the iliac graft into the host bone. Note that while the density of the graft and radial fragments is the same, the ground glass-like appearance of iliac bone has not been lost at this time and the reformation of a medullary canal is not yet manifest roentgenographically.

for this complication always exists in this type of battle injury even with the best preparation and technique) the presence of foreign bodies will serve to encourage and perpetuate such an infection.

The technique of the plate-graft procedure has been described at length in the authors' original communication. They have found it of considerable advantage to utilize the electric knife and cautery in exposing the fracture and preparing the field for the graft and they have used this technique in exposing and removing grafts from the ilium. Both fields are kept dry by the use of continuous suction.

Although the soft tissues which have been dissected from both tables of the ilium are resutured with care following removal of graft material and despite hemostasis by the electric coagulator and the use of bone wax to control bone bleeding, ecchymosis and, in some cases, hematoma formation may occur. The latter has been controlled without any ill effect by early aspiration. The writers who have attempted a second removal of bone from the same ilium in 2 cases and encountered

considerable difficulty due to scarring and soft tissue adherence at the site of the bone defect, caution against this procedure and advise the use of the opposite ilium instead. These findings may account for the lack of residual disability following the resection of even massive portions from one or both ilia. There has been no instance of herniation through the iliac wound. The ilium at the site of resection will tend to regenerate, although defects are seen to persist in late postoperative roentgenograms.

Femur cases are brought to the operating room in their traction-suspension and are operated upon with the weight applied continuously to the pin through the distal end of the femur or the proximal end of the tibia. In the instance of other long bones a plaster-of-Paris support is applied several days before surgery and is bivalved to permit immediate application postoperatively, and this external fixator is usually changed 3 weeks postoperatively. The positioning of the patient at the time of surgery will depend entirely on the site of approach selected for the involved bone and depending on this position either the right or left ilium is used. For this reason both iliac crests are prepared preoperatively.

When necessary the patient is prepared with whole blood transfusions preoperatively and in all cases blood is administered during the operation. Usually 1,000 cubic centimeters is administered to femur and humerus cases and 500 cubic centimeters in operations on other long bones which permit the use of a tourniquet. The procedure can be greatly hastened by the use of two teams. In the last 5 months of this study the senior author found it necessary to prepare the field for the graft and to remove the graft himself. Despite this the procedure has not become complicated and operation upon some of the most difficult femur cases has not exceeded 2½ hours. With a two-team technique the operation on the femur has been completed well within a 2 hour period.

Penicillin has been employed systematically in all cases, in doses of 20,000 units every 4 hours and more recently in doses of 40,000 units every 4 hours. Administration is begun at 6 p.m. on the evening before surgery and

continued for a minimum of 5 days and in cases requiring extensive surgery for 10 days postoperatively.

As originally described in the instance of the femur this long bone is exposed and a six screw plate is applied on the side of greatest stress which is usually lateral as manifested by the tendency for lateral bowing in most instances. It is essential that a plate of adequate length be employed with a minimum of two screws above and two screws below the fracture level which screws must include both cortices of the host bone. The authors have employed washers fashioned from metallic plates where it has been necessary to remove the hard outer table in reshaping the iliac graft and to assure a more adequate purchase of the screws. All metallic bodies have been constructed of stainless steel. Prior to the application of the graft a trough is constructed and the medullary cavities of both fracture fragments are opened. This is done anteriorly or laterally depending on which side the plate has been applied. This cavity is filled with long strips of iliac bone and the massive iliac graft is then applied across this area and is fixed with one or two screws above and below the fracture level. It has been found advantageous to recess and to countersink this massive graft for this assures more adequate contact with the host bone and what is very important in cases in which there has been considerable scarring facilitates closure of the overlying tissues without tension. Prior to the application of the graft the ends of the fragments may be drilled. Long strips of iliac bone are placed across the exposed surfaces of the fracture. Except where it is necessary to remove tissue for exposure and graft application the scar between the fragment ends is not resected and the fragments are not unduly exposed.

It was the authors' experience very early in the surgery of ununited battle fractures that the presence of marked scarring created difficulty not only in exposure but also in closure. Any attempt to close these wounds under tension may result in breaking down of soft tissues or create a dead space which encourages hematoma formation and the danger of secondary infection. It was also obvious that

Fig. 9 Compound comminuted fracture of the tibia, incurred in battle, with residual nonunion and a gap defect of 3 inches (7.5 cms.). Operation was performed 6 months following the cessation of all drainage and after preliminary scar excision and the gap was bridged by a massive, full thickness iliac graft. The fibula was intact and a metallic plate was not applied. The illustration shows the roentgenographic appearance of the iliac graft 5 months post-operatively. Clinically the leg was quite stable. At the time that this report was completed the extremity was protected in an Ischial weight bearing brace with a molded leather cuff for the leg.

if an effort was made to expose the fragments freely and to attempt to correct overriding or bowing deformities closure became difficult or impossible. For this reason except in a few instances where the fragment ends have been widely separated the usual procedure has been to disturb the position of the fragments very little or not at all and to expose them just sufficiently to permit application of the plate and countersunk graft provided of course that the general alignment of the axes of the fragments has been satisfactory.

Where the graft is employed without plate fixation it is adequately shaped and is fixed with two screws above and two below the fracture level. The manner of fixation of the graft will vary depending on the mechanical requirements in each case and this must be anticipated from the roentgenograms preoperatively and determined accurately at the operating table. It is preferred to apply grafts on the most vascular side that is away from scar and on the side most heavily muscled.

Fig. 10. Line drawings illustrating methods of shaping grafts for nonunion with defects in single forearm bones or in the tibia. a, Flange graft. b, Graft step-out and recessed at each end. c, d, Trapezoid and parallelogram-shaped grafts to fit oblique ends of fracture fragments.

e and f, Fixation of the long oblique type of ununited fracture by multiple transfixion screws, with application of the bone graft at right angles to the direction of these screws.

g and h, Valgus deformity of the ankle and foot following malunion at the distal end of the tibia. Resection of wedge, shaped so as to create, in effect, an oblique type of fracture which is fixed with several screws. The concept of this type of osteotomy is based on the success following multiple-screw fixation in the treatment of the acute type of long oblique fracture when open reduction is indicated, as well as in the treatment of similarly shaped ununited fractures as illustrated in e and f.

In the instance of a nonunion at the distal end of the radius, it has usually been found advisable for adequate purchase of the graft to bridge both nonunion and the wrist joint simultaneously and thereby to effect both healing of the ununited fracture and wrist fusion. In one instance of ununited fracture of the radius and another in the femur the distal fragments were so severely porotic that a good purchase of the graft could not have been secured with screws and the grafts were driven

into and thoroughly impacted within the distal fragments.

The flange graft devised by the author for the filling of defects particularly of forearm bones, is shaped from the crest of the tibia in such a way that its body accurately fits in and fills defects up to 5 centimeters in length while its ends are shaped into flanges of about 2.5 centimeters in length for lateral application to the fracture fragments with screw above and below the gap-defect. Another type of iliac graft employed to fill large defects includes one table (for forearm bones) or two tables (for the tibia) and is applied by step-cutting its ends and mortising these into recessions at the ends of the fracture fragments where they are fixed with screws. A trapezoid-shaped graft or a parallelogram-shaped graft is best suited to fill a defect where the fragment ends are oblique (Fig. 10, a, b, c and d).

Rigid fixation has been satisfactorily obtained in long oblique fractures by the use of 2 or 3 transfixion screws across the oblique fracture after baring the ends and reshaping them for accurate contact and the graft is applied at right angles to these screws (Fig. 10, e and f). This technique has been employed in 5 cases, 3 times in the ulna and twice in the tibia with excellent union in all instances. In association with this experience a method of osteotomy has been developed for the treatment of malunited fractures of long bones wherein a wedge of bone is excised in such a manner that not only is the existing deformity corrected but also a long oblique type of fracture is created which is held securely by two or three transfixion screws (Fig. 10, g and h). This procedure has been successfully performed on 6 patients, 3 in the tibia, 2 in the radius and 1 in the ulna.

The usual approaches, that is, lateral and posterolateral for the femur, anterolateral for the humerus, posterior for the forearm (performed best with the arm across the chest) and anteromedial or anterior for the tibia, have had to be varied in some of these cases. It is presupposed that every effort will be made to replace inadequate skin through plastic surgery prior to the bone graft. This is essential especially if the approach must be made through or close to such an area, and also to

insure adequate nutrition of the fracture and the graft. The unfortunate fact however is that soft tissue scarring is often so severe that even such replacement of skin and subcutaneous tissue does not eliminate the massive scarring of the deeper tissues which may extend down to the bone itself. In such cases it has been advantageous to approach the long bone through more normal tissue and thus to completely avoid the severely scarred area. For example an anterolateral approach to the tibia has permitted good exposure of the lateral aspect of the tibia and application of the graft on that side while in one instance in the upper third of the leg it has permitted the additional medial shifting of the fibula and its transfixion to the tibia. In two tibial cases presenting severe anterior scarring despite previous pedicle skin grafts a posterolateral approach was employed and the grafts were applied to the posterior surface of the tibia. However exposure was found to be very limited and in one case the graft could be transfixed with only one screw above and one below the fracture level while in the other case the graft was placed in the prepared site across the fracture without screw fixation. It is therefore an approach that is not recommended as routine procedure but which may serve to advantage in this type of case.

4. Incidence and factors involved in failure of the graft operation—an evaluation of results up to March 15, 1946. A total of 91 bone graft operations have been performed on 85 patients. Of these 34 have been by the combined plate-graft technique and include 31 operated on with plate and cancellous bone graft, 2 with plate and cortical graft (both in femurs with massive defects and nonunion) and 1 case with an ununited fracture of the neck of the femur in which the cortical grafts were combined with fixation by a Smith Petersen nail. The site of operation was as follows: shaft of the femur in 22, neck of the femur in 1, radius and ulna in 5, humerus in 3, and tibia and fibula in 3. In 57 operations grafts were used alone with simple screw fixation and of these 54 had iliac grafts, 1 femur case with massive defect had combined cancellous and cortical grafts and 1 case with a gap-defect in the humerus had two cortical graft operations.

The site of operation in this group of cases was as follows: tibia in 16, radius in 13, ulna in 12, femur in 7, humerus in 5, spine of the scapula in 1, and clavicle in 1.

Massive defects of bone complicated the ununited fractures and exaggerated the complexity of their reconstruction in 29 cases. The bones were involved as follows: femur in 10, radius in 8, tibia in 4, ulna in 4, and humerus in 3. On the other hand bone grafts were employed in the treatment of massive defects which were bridged by a narrow bony strut in only 8 cases: 5 in the femur, 1 in the humerus, 1 in the tibia and 1 in the radius. Adequate time should be allowed to permit hypertrophy of the existing strut and the authors have been amazed how often patients listed as potential candidates for bone replacements have demonstrated after observation for several months sufficient bone reformation so as not to require surgical interference. Experience with reference to the incidence of postoperative infection following reconstructive bone surgery in battle casualties which will be discussed later further justifies this conservative attitude. Large defects in the upper end of the femur and humerus where the effect of the lever action of the extremity may prove very vicious warrant consideration for surgery earlier than those defects of long bones distal to these levels. One must be guided by the size of the original bony strut bridging the defect, the progress of its hypertrophy during the ensuing months and whether or not the defect is protected by an intact adjacent bone as in the forearm and leg.

An analysis of the plate-graft group indicates that definite union occurred in 20 cases observed for 4 months postoperatively or longer and definite nonunion occurred in 2. One nonunion occurred as the result of faulty technique and has since been reoperated upon while the other followed a postoperative infection. Satisfactory union was progressing in 8 cases observed over 10 weeks postoperatively in whom the extremities were still protected in braces or casts while in 4 cases all femurs it was too early to evaluate the probable end results at the time that this analysis was completed. In 3 of these the postopera-

TABLE I.—RESULTS OF 91 BONE GRAFT OPERATIONS IN 83 PATIENTS

Performed between September 1, 1944 and March 1, 1946 and evaluated up to March 5, 1946

tive course has been most satisfactory while in one case the presence of a very mild post operative infection left the fate of the graft in doubt (Table I).

In the patients treated by grafting without plate fixation 28 fractures were definitely united 4 months or more postoperatively while in 6 patients there was definite recurrence of nonunion. Four of the recurrences were the result of errors in technique and were subsequently reoperated upon and two recurrences followed postoperative infections.

A fracture of the bony strut in another patient following a bone replacement operation for massive femoral defect necessitated a second bone graft. Union had progressed satisfactorily in 17 cases observed for more than 10 weeks postoperatively while it was too early to determine the course in 5 cases observed for less than 10 weeks at the time of this final analysis. In only one of these because of a mild postoperative infection was there any doubt as to the fate of the bone graft (Table I).

In the 8 cases of massive defects with union replacement surgery was by massive iliac grafts alone. In one of these a defect in the upper third of the femur a fracture occurred through the narrow bony strut, although the

patient was still in suspension. He was reoperated upon by the combined plate-graft technique, and this instance served to impress the authors with the wisdom of utilizing plate fixation in addition to bone replacement in the treatment of massive defects, even in the presence of some union in the upper end of the femur and humerus.

The authors can speak with certainty of an incidence of 9 failures of initial bone grafts by their technique, while in 2 other cases, both of whom had mild postoperative infections and had been observed less than 10 weeks, the fate of the graft could not be accurately determined at the time that this study was completed. Of the 9 definite failures, 3 were incidental to postoperative infections which required the removal of plate and graft, while 6 were the result of faulty technique. Five of these 6 cases, who had had cancellous grafts were reoperated upon and progressed or were progressing to satisfactory union. In 4 of these patients the recurrences were due to failure to use a plate along with the graft. One was a nonunion of both bones of the forearm, another a nonunion of the surgical neck of the humerus, and the third and fourth were defects in the upper half of the femur. In a fifth case with ununited fractures of both

bones of the forearm the plate-graft technique had been used but the plate had been too short and had not bridged the gap-defect satisfactorily. The one cortical graft failure was the case previously referred to with a massive defect in the upper end of the humerus and absence of the humeral head and glenoid in whom a fibular graft had been initially employed with gradual resorption at its center and in whom at reoperation a tibial graft was applied across the fibular fragments (Fig. 4). The authors suggest that a fibular graft so used should not have multiple drill holes placed in its central portion as recommended to enhance its revascularization for they feel that this may encourage resorption and fracture in this region. They also feel that this hazard may be lessened by the additional use of slivers of iliac bones, placed along the surface of the cortical graft.

The authors feel that the end results in the last 9 cases, performed during January and February 1946 could not be evaluated accurately at the time of this report. There have been therefore 9 failures following 82 initial bone graft operations in a series of 76 patients who have been observed a sufficient length of time varying from 10 weeks to 18 months and this represents an incidence of 10.8 per cent. Six of these 9 failures have been successfully reoperated upon—a total of 79 successful unions and 3 failures as evaluated up to March 15 1946 (Table I).

It has been experienced widely that the use of a plate for internal fixation of long bone fractures particularly of the transverse type will encourage delayed union and even non union since the plate tends to hold the fragments apart and appears to discourage callus formation on the side to which it is applied. Six cases in this series were simple fractures of the femur which had been treated early by open reduction and plate fixation and the occurrence of nonunion in these cases was unquestionably influenced by the use of these plates. The performance of iliac bone graft operations was greatly facilitated in these instances by the fact that the plate had already been applied and the bone fragments were well positioned and since the fractures had been simple dissection was performed with

ease along anatomical planes. Union occurred in all six cases, and was sufficiently firm in one instance, 5 months postoperatively to permit full weight bearing. The authors feel very strongly that the plate-graft technique will find eminent success in its use in ununited fractures in civil practice where many of the fractures have been simple and those that are compound present few of the complexities of battle fractures. They feel that the vicious features of plating as employed in the internal fixation of acute fractures do not apply in the combined plate-graft technique and that the only dangers involved are those incidental to the introduction of an inert metallic substance. The value of rigid fixation in the successful grafting of complicated ununited fractures of long bones as herein reported more than justifies the continued use of metallic plates and screws.

5 Incidence and factors involved in the occurrence of postoperative infection following iliac grafts in the presence of infection. The authors have elected to wait at least 6 months following the cessation of all drainage before attempting any reconstructive bone surgery. This period represents a longer waiting interval than that accepted by other orthopedic surgeons but the authors believe that the hazards of postoperative infection and of failure of bone grafting are exaggerated by such haste and the question in their minds at this time is whether a 6 months waiting period is sufficiently long.

In this series, postoperative infections occurred in 11 out of 91 operations or 12.1 per cent. The local infection was moderately severe in only 1 case requiring removal of the plate and graft 2 weeks postoperatively and it was mild or moderate in the remaining 10 cases. Surgical interference could be safely deferred in these 10 cases for 4 to 6 weeks or more postoperatively with control by penicillin and early drainage without hazard to the patient. Six of these 10 patients have been operated on and plates and screws removed in 3 (2 femurs 1 tibia) and the screws alone in the remainder (2 radii 1 ulna). Two others, both femurs, were well united but persisting drainage 4 months postoperatively in both indicated the need for subsequent removal of

plates and screws. In 2 others a femur and a tibia the postoperative period of 8 weeks was considered too short for proper evaluation of the ultimate fate of the graft and removal of the metallic bodies had been deferred.

In 6 of the mild or moderately infected cases 4 ununited fractures of the femur 1 of the radius and 1 of the tibia, union occurred with incorporation of the major portion of the graft. Failure of union occurred in 2 more both of whom originally demonstrated large gaps, but the graft became incorporated into one of the fracture fragments. In other words where the infection had been mild enough to warrant delay in surgical interference (in 10 of the 11 cases) the graft became incorporated with union in 6 and became incorporated but with recurrence of nonunion in 2 more. The fate of the graft was in doubt in the remaining 2 cases at the time that this study was completed.

Definite failure of union following iliac bone grafting occurred in 3 cases in this entire series as a result of infection *per se*. *Postoperative infection therefore although a most undesirable complication does not mean failure of an iliac bone graft if surgical interference can be sufficiently delayed.* The authors believe that this is more apt to occur with iliac bone as graft material because this type of graft is so rapidly invaded by new bone and incorporated into the host bone.

One cannot deny that once infection has occurred the metallic bodies employed for internal fixation although inert act by their presence to perpetuate the infection and this applies whether stainless steel plates and screws or just screws alone have been employed. The only patient in whom the infection subsided spontaneously had had an iliac bone graft to fill a large defect in the tibia and this graft had been firmly mortised into the defect without screw fixation.

Nevertheless although the presence of metallic fixation presents this untoward feature the advantage of plate fixation is striking even in this group of cases. Of the 6 cases wherein union occurred in the presence of infection 4 were ununited fractures of the femur and had had the combined plate-graft operation. The plates served to maintain rigid fix-

tion at the operative site and preserved the alignment of the bone fragments until union had occurred and the foreign bodies could be safely removed.

The authors believe that these postoperative infections are not the result of faulty technique and offer as proof the absence of a section of the donor wounds in any of their cases. The incidence of infection reported herein parallels that recorded in other military installations. These battle fractures have been severely compound, they have been associated often with considerable soft tissue damage and drainage has persisted for variable periods prior to complete healing. The background as well as the condition of the involved extremity at the time of surgery is altered circulation, skin and soft tissue scarring and bony deformity influence and encourage the occurrence of postoperative complications. It must be emphasized that in all of the cases presenting postoperative infection in this series there had been previous infection and osteomyelitis (compound battle fractures with drainage) and that this complication did not occur in any previously uninfected case.

The authors call attention to a factor which has received little or no attention viz the existence of living organisms at the site of original injury even in the absence of drainage from 6 months to one year. Cultures were made at the time of bone graft surgery in a group of 18 cases. These cases had not drained for at least 6 months and had adequate penicillin and sulfonamide therapy following the initial injury and at the time of bone grafting. Also the gross appearance of the field at the time of exposure was satisfactory i.e., there were no areas of necrosis, no dead fragments and no evidence of any inflammatory process. Positive cultures were reported in 9 cases or 50 per cent! Those patients with negative reports had an uneventful convalescence. Of the 9 patients with positive wound cultures one had been a simple fracture of the humerus with failure of union following open reduction and plating while the 8 remaining cases had been compound fractures, and all 9 cases demonstrated definite wound reaction postoperatively. Redness and induration of the wound occurred in 2 cases for 1 to 2 weeks postopera-

tively and then subsided (Staphylococcus albus 1 Staphylococcus aureus 1) seepage persisted for 2 weeks in 1 case and then subsided completely (Micrococcus spheroides) while mild drainage occurred in 5 the wounds requiring dependent drainage several days postoperatively (Staphylococcus albus 2 Streptococcus hemolyticus 1 Staphylococcus aureus 1) There was no reaction of the donor wound in any of these cases. While this series is far too small to render significant percent ages it is important to realize that there are battle fractures requiring reconstructive surgery which under present standards have been considered adequately prepared for such surgery wherein living organisms have been cultured and that such cases have manifested uniformly definite local wound reactions and in some instances actual postoperative drainage

The incidence of positive cultures might very well be higher in series where a shorter period than 6 months has been arbitrarily accepted as a sufficient waiting period. How may extension of the waiting period beyond 6 months lessen this hazard? Two of the cases yielded positive growths after waiting periods of 9 months and 1 year respectively! While there is no means at this time to determine the presence of living bacteria at the site of intended surgery either prior to or at the time of surgery a positive culture will at least serve to put the surgeon on guard. Penicillin and sulfa sensitivity tests may serve to guide him in the use of these or other agents. Because of the inability at this time to determine the presence of living bacteria prior to or during surgery or to protect against or to eliminate this factor effectively the authors have concluded that there will continue to be an irreducible minimum incidence of postoperative infection following bone graft or other reconstructive surgery of battle fractures.

CONCLUSIONS

- 1 The principle forte for the use of iliac bone has been the fact that it is cancellous and therefore accessible to rapid revascularization and that it is richly osteogenic. There is reason to believe that some of the iliac bone survives in contrast to a cortical graft, and the remainder becomes rapidly invaded by

new bone. Iliac bone grafts maintain a density on roentgenograms which is comparable to that of the host bone and the relationship does not change with time.

A point to be considered in the use of iliac bone is whether the cancellous ilium undergoes metaplasia to assume an architecture capable of sustaining the stresses and strains of weight bearing and muscle pull and what time element is involved. Roentgenograms appear to show evidence of such metaplasia beginning at about 12 weeks after implantation while roentgenograms at 6 months and longer show the grafts to be practically indistinguishable from the adjacent cortical bone.

Resorption of iliac grafts has occurred as late as 4 or 5 months postoperatively due possibly to incomplete metaplasia and structural weakness of the graft and the result of stress and strain upon an inadequately protected graft. This also occurs with cortical grafts and is one of the dominant reasons for the use of internal metallic fixation in conjunction with grafting procedures.

- 2 There are certain instances where cortical bone must be employed for example where grafts must be excessively long and in cases in which an absolutely straight, rigid segment of bone is required.

- 3 To assure absolutely rigid protection during the phase of graft incorporation especially where large defects are being bridged it is recommended that the plate graft technique be employed in the surgery of nonunion and massive defects of single long bones as the femur and humerus and in the presence of nonunion of both bones of the forearm and leg. Where one of the bones of the forearm is intact and in the leg in the presence of an intact fibula the graft alone held with two or more screws above and below the level of the fracture offers adequate fixation.

4. The technique of plate-graft application and of fixation of the graft when used alone without a plate must be varied to meet the mechanical requirements in each case. Incisions may have to be varied depending on the degree and site of soft tissue scarring. The oblique type of fracture lends itself very well to simple transfixion with the use of multiple screws.

5 Failure of the bone graft operation with recurrence of nonunion excluding those cases associated with postoperative infections, has been due to such errors in technique as failure to use a plate when specifically indicated and failure to use a plate of adequate length

6 Postoperative infection does not mean failure of iliac graft incorporation especially if the infection is mild and well controlled and removal of the metallic fixation can be deferred

In an effort to account for this complication the authors place much significance upon the

fact that in a certain number of battle fractures active growths of bacteria have been cultured from the site of original wounding six months to one year following the cessation of all drainage. Since there is no way at this time, to determine accurately the presence of living bacteria at the site of injury prior to or at the time of surgery or to eliminate the factor effectively the authors have concluded that there will continue to be an irreducible minimum incidence of postoperative infection following bone graft or other reconstructive bone surgery of battle fractures.

COAGULATION THROMBI IN SEGMENTS OF ARTERY AND VEIN IN DOGS AND THE GENESIS OF THROMBOEMBOLISM

ALFRID L. COPIEY M.D. and PAUL L. STEFKO B.A. New York New York

SINCE the early experiments of William Hewson it is known that blood remains liquid for a long period of time between ligatures in a vein segment. This phenomenon was further studied by Baumgarten. He found that when the double ligature is applied under antiseptic precautions and the wound heals aseptically the included blood column remains liquid. On the other hand such experiments without antiseptic precautions resulted in coagulation, a fact which has been confirmed by Senfleben in Cohnheim's laboratory.

Our problem was to investigate whether tissue juice from vein of homologous and heterologous origin would coagulate the stagnant blood within a formed vessel segment *in vivo*. This study was of special interest because it has been claimed that the endothelial lining prevents coagulation. We studied further the effect of human placental thromboplastin (10) on the formation of coagulation thrombi. Our observation also yielded information about the adhesiveness and syneresis of a blood coagulum formed within arterial and venous vessel chambers *in vivo*. The experiments were performed in healthy young mongrel dogs.

Because of the basic nature of these investigations pertaining to the phenomenon of thrombus formation and more recent studies on the phenomenon of platelet agglutination a discussion of thrombosis and of thromboembolism becomes necessary.

EXPERIMENTS

Procedure The carotid artery is dissected free for approximately 8 centimeters and occluded with rubber shod clamps first proximally then distally. A 25 gauge needle is intro-

duced at the proximal end, care being taken not to injure the artery more than necessary. Blood is withdrawn from the occluded vessel segment into a syringe and the volume noted. One-tenth cubic centimeter of tissue juice or thromboplastin is introduced into the vessel segment. The needle is removed, the proximal clamp is released to allow the segment to fill with blood and the vessel is clamped over the orifice made by the needle. After an incubation period of from 1 to 9 minutes the vessel is excised immediately and placed on filter paper. Both clamps are removed and the vessel is cut along its long axis. The formation of the coagulum is noted carefully. As a control the coagulant agent is replaced by 0.1 cubic centimeter of saline and the above procedure followed.

Results Figure 1 shows in full size photograph a resected vein segment containing the coagulation thrombus. The photograph illustrates that there is no adhesiveness of the thrombus to the vessel wall. Upon removing the clamps the thrombus emerged freely without mechanical or manual manipulation. A small amount of serosanguineous liquid was present, apparently exhibiting syneresis.

Figure 2, an artery segment (full size), has been opened along its long axis to illustrate syneresis of the thrombus. This phenomenon is especially evident if one compares the length of the vessel with the length of the thrombus. On both ends of the segment one also can observe marked areas which are due to staining of the filter paper with serosanguineous liquid.

Table I shows results in 6 vein segments, 5 of which resulted in thrombus formation with an incubation time of 5 minutes whereas 1 with an incubation time of 3 minutes did not exhibit coagulation. Table II presents the effects of vein juice from dogs and chickens on the formation of coagulation thrombi. In 7

f = complete

segments employing vein juice from dogs 4 coagulated completely after 15 and 3 minutes whereas partial coagulation was formed in 2 segments following 2 minutes and in 1 following 3 minutes incubation time. Partial coagulation is designated by a coagulum which is mixed with coagulable whole blood. This is readily differentiated from serosanguineous liquid as obtained by syneresis by (a) its color (b) the fact that it coagulates on standing (c) its consistency in that it does not exhibit complete blood gelation but rather fibrin threads with or without gel formation.

Vein juice from chickens was employed in 6 segments resulting in partial coagulation after 1 and 2 minutes and complete coagulation after 4 and 5 minutes.

From Tables I and II it also can be seen that there are relatively large volumes of the test material as compared to the blood volume used in the arteries. This relationship, however, does not necessarily influence the coagulation time as may be seen in Table II. In dogs 902 and 828 both blood volumes were large and both test materials amounted to 1 cubic centimeter of the blood volume yet partial

Fig. 1 Coagulation thrombus in vein segment.

Fig. 2 Coagulation thrombus in artery segment.

tial coagulation was observed after 2 minutes in dog 902 and complete coagulation was found after 15 minutes in dog 828. Similarly in dog 922 with a blood volume of 0.2 cubic centimeter and 0.1 cubic centimeter of test material coagulation was observed after 4 minutes. On the other hand with a blood volume of 0.9 cubic centimeter and 0.1 cubic centimeter test material partial coagulation was found after 2 minutes in dog 840.

In comparing Tables I and II no conclusion can be made whether or not coagulation is enhanced in arterial or in venous segments. Only in 1 instance in a vein segment of dog 916 was the incubation time found to be less than 5 minutes.

Table III lists the controls physiologic saline being used in 6 artery and 4 vein segments. No coagulation occurred in the controls after 5 to 9 minutes incubation time.

The effect of Copley's preparation of purified thromboplastin from human placenta (10) upon coagulation thrombi is summarized in Table IV. Eight carotid arteries, 5 femoral arteries, and 16 jugular veins were employed. Coagulation occurred in all instances except in 1 jugular vein segment with an incubation time of 1 minute. Another such segment of uniform length blood volume and amount of thromboplastin exhibited coagulation following the same incubation time. All coagulation thrombi exhibited syneresis and no adhesiveness to the vessel wall. It should be noted that in all cases the coagulation was complete.

Of interest is the comparison between length of the vessel segment and its blood volume. Vessel segments of 45 to 72 millimeters in length were used.

In all our observations on coagulation thrombi syneresis was always found even

though the incubation time of the test material with whole blood was as short as 1 minute. From this one may infer that syneresis occurs rather immediately following coagulation with in a vessel segment. Adhesiveness to the vessel wall was absent in all artery and vein segments in which coagulation thrombi had formed (Tables I, II, and IV).

Table V shows the results of several manipulations on the blood vessel such as clamping it along the entire segment applying a double silk ligature insertion of a needle into the lumen pinching with forceps along the entire segment and crushing over silk with a hemostat. In 9 artery segments clamping with a hemostat after an incubation time of 5 to 8 minutes did not result in coagulation. In dog 924 the jugular vein was isolated for approximately 5 centimeters and ligated at its distal and proximal ends. This segment containing the column of blood was incubated for 18

hours, during which time its coagulable blood did not coagulate. In 2 vein segments a needle was inserted with a stylet in place and allowed to incubate in the stagnant blood column for 5 minutes. After this period of time the blood was not coagulated. In 2 vein segments, the blood was milked out of the segment manually and the vein crushed with a hemostat along the entire segment. The proximal clamp was then released to permit the vessel chamber to fill with blood. After an incubation time of 10 minutes no coagulation occurred.

Upon longitudinal section of the vein segment definite areas of injury to the intima were observed macroscopically. The same effect was also obtained in 6 out of 8 vein segments which were crushed over silk according to the procedure of Murray (20). The incubation times were 10 minutes in 3 cases, 3, 30 and 36 hours in each one case with no coagulant effect. However in 2 cases in which incubation times were 24 and 48 hours coagulation occurred and syneresis and nonadherence of the coagulation thrombi were found.

DISCUSSION

1. *Physical properties of coagulation thrombi*
Our observations are of fundamental significance since they give evidence that a blood

coagulum which is produced intra-arterially or intravenously without infection is a coagulation thrombus which is not adherent to the vessel wall and moreover exhibits syneresis (clot retraction). These latter phenomena nonadherence and syneresis of a noninfected coagulation thrombus, together with clot firmness are the basis for the thromboembolic disease. It stands to reason that a clot that does not fill a vessel segment completely because of syneresis and which is not otherwise adherent to the vessel wall is likely to become an embolus. Recently the differentiation between phlebothrombosis and thrombophlebitis has been stressed by several surgeons, especially by Ochsner and DeBakey. In phlebothrombosis or the so-called quiet venous thrombosis of Homans a soft nonobstructive clot exists which increases the danger of embolism. In thrombophlebitis, on the other hand the clot has been found usually firmly adherent to the vein wall and is therefore less likely to become detached and result in embolism. This contention as far as the noninfected vessel wall is concerned, can be supported by our findings. We have not made any observations on the adherence and syneresis in infected vessel segments. Moreover we found this phenomenon was present not only in vein segments but also in arteries.

The firmness of coagulation thrombi has not been studied. However there can be wide variations in firmness of coagula of human blood as has been shown by Lalich and Copley (18) with a special viscometer. No correlation has been found between firmness and retraction of a blood coagulum according to Copley (9).

Attempts have been made by Vigyazo to produce experimentally clotting in segments of varicose veins in man. The resulting thrombus was a red or coagulation thrombus which was not adherent to the vein wall. Some clot adherence was only found after several days following the production of the thrombus. This latter observation was already made in 1856 by Virchow. He found that blood coagula are free during the first time following their production. Only later with the onset

of chemical and morphological changes stickiness occurs between them and the surrounding tissue. Virchow observed this in apoplectic extravasates of all organs in the clots of aneurysms and in the occluding plugs of veins.

2 Injury to the vessel wall and thrombus formation. Baumgarten observed that the complete stasis of the blood in a vessel segment does not necessarily lead to thrombus formation. He found that no coagulation occurred even if the intima is damaged because of the ligation. His experiments were carried out in arteries and veins of dogs, rabbits and guinea pigs under aseptic conditions. In our experiments we found thrombi only in 2 out of 8 cases of severe injury (crushing over silk) to the vessel wall. No thrombi developed in 5 other instances with less injury to the vessel

wall. Our investigations suggest that the incubation period following injury may affect the formation of a coagulation thrombus.

The results show that crushing over silk in stagnant blood columns does not always produce coagulation thrombi. With circulating blood it has been shown by Murray and associates (19) that white thrombi occur at the site of the injured vessel wall. However in earlier investigations Welch claimed that it is possible to produce experimentally severe injury of the internal coats of blood vessels without any resulting thrombosis.

One may argue whether or not the lesion of the endothelial cells or a dysfunction of the cells as it was assumed by Cohnheim in 1882 would result in thrombosis. Bizzozero observed that in causing slight damage to the inner surface of an arterial wall in small mammals a so-called white thrombus was formed which consisted almost entirely of blood platelets. Later in 1886 Eberth and Schimmelbusch found that in damaged blood vessels first a white thrombus occurs which is mainly a platelet thrombus which may contain white blood cells. Upon this primary formation of a thrombus a second so-called red thrombus forms which is coagulated whole blood. Best, Cowan and MacLean found that when a shunt, composed of glass or cellophane tubing is inserted between an artery and a vein in anesthetized dogs, cats, monkeys and rabbits large white thrombi rapidly form and in many cases completely obstruct the flow of blood. These thrombi usually grow downstream rather than upstream from the original focus. Subsequently to the white thrombus a red thrombus forms. These observations made in artificial vessel segments concur with the classical observations.

In the injured vessel in which the flow of blood is not completely and primarily blocked platelets will adhere to the injured vessel wall and form platelet or white thrombi. This process may be enhanced by the infusion of tissue juice through the lesion in the vessel wall since Copley and Houlihan (12, 13) have shown that tissue juice does agglutinate platelets although purified thromboplastin does not. An admixture of tissue juice is apparently not necessary to form white thrombi ac-

cording to the experiments of Best, Cowan and MacLean in artificial glass and cellophane shunts. However in injured blood vessel tissue juice may well enhance the formation of white or mixed thrombi. This process may be further augmented in infected or diseased vessels because of the infusion of large amounts of tissue juice.

More recently Chambers and Zwerbach made the observation that the interendothelial cement is sticky and offers considerable surface on the inner lining of the endothelium to which formed particles adhere. Whether or not defects in this lining or deficiencies of the substance comprising the interendothelial material would influence the formation of coagulation thrombi and agglutination thrombi will have to be decided in future experimentation. It is possible that the cement substance may itself contain a platelet agglutinant factor.

3. *The nature of intravascular blood clotting.* Blood clotting can no longer be considered primarily as the coagulation of whole blood, because of the recent observations on the mechanism of platelet agglutination (12, 13). Is the following schema developed by Copley (11) the phenomenon of blood clotting is presented in all its possible occurrences.

Blood clotting according to the point of view presented in the schema is a general term for either plasma coagulation, cell agglutination and clotting in which both phenomena are mixed. As plasma coagulation is understood that the precipitation of fibrin is synonymous with blood coagulation. This process may ultimately terminate in gelation of the blood plasma or the fibrin respectively. In the schema gelation is shown to occur with or without preceding fibrin formation.

It is not the scope of this presentation to discuss the mechanisms of fibrin formation and gelation. The phenomenon of cell agglutination is subdivided into agglutination of platelets, red and white cells. The agglutination of white cells which is known to occur appears to be insignificant because of the small number of white cells in normal blood. White cells may be agglutinated with platelets *in vivo* forming the so-called white thrombi. In *in vitro* forming the so-called white thrombi. Is red cell agglutination immunologic reactions are prevalent however red cells may aggluti-

ate with preceding fibrin formation as it is shown in polycythemia vera. Platelet agglutination occurs without preceding fibrin formation and appears with or without subsequent fibrin formation. Whether or not immunologic reactions take place in the agglutination of platelets will have to be decided in future investigations. From this schema it is furthermore proposed to define thrombosis or thrombus formation as intravascular blood clotting during life.

This schema helps us to understand the differentiation between coagulation thrombosis as produced in our investigations and the agglutination thrombosis or mixed thrombosis is produced by Best, Murray and associates and earlier in the classical observations by a number of workers. The injured vessel segment does not readily produce coagulation thrombosis, because apparently in a noninfected blood vessel, not sufficient tissue juice containing thromboplastin would infuse into the segment as to initiate by its content of

thromboplastin blood coagulation. In infected and edematous vessel segments coagulation thrombosis may possibly occur in a stagnant vessel chamber because sufficient tissue juice containing enough thromboplastin could enter the chamber and produce coagulation. It should be emphasized that tissue juice is not identical with thromboplastin although the latter substance is one of the constituents of tissue juice.

It may be inferred that the generally accepted differentiation between infected and noninfected thrombosis does not suffice. For a more advanced approach of various problems pertaining to thrombosis including effective therapy one should keep in mind the presented differentiation given in the schema. This presentation does not claim to include all possible influences and factors on thrombus formation however. It is meant to be a guide for a better understanding of the problem of thrombosis. The general contention that thrombus formation in itself constitutes solely a coagulation phenomenon is theoretically no longer tenable.

4 *The genesis of thromboembolism*. According to Bauer emboli occur within 24 to 48 hours after thrombus formation in veins. During this time the wall of the vein is as yet not involved in any way and the thrombus is anchored only. This observation corroborates our findings that coagulation thrombi are not adherent to the vessel wall and are at the same time synergetic both of which are of potential danger in the genesis of embolism.

The findings of Best, Cowan and MacLean that white thrombi which are noninfected may break off easily appear to be of significance. Coagulation thrombi and agglutination thrombi may well become adherent to injured walls of infected blood vessels. The firmness of these thrombi under both infected and noninfected conditions will have to be investigated.

It should be emphasized that slowing of the blood stream, damage to the vascular endothelium and changes in the blood must be regarded as causes of thrombosis. This view has been accepted by Aschoff in his latest publications on this subject (1, 2). Of interest are the observations of Copley, Kirschman and Whitney (14) who studied the anomalous flow proper

deficits described the general and neurological examinations gave normal findings. There was total motor paralysis of both lower extremities except for the ability to move the left large toe slightly. The patellar and Achilles tendon reflexes were hyperactive. There was patellar and ankle clonus and the Babinski sign on both sides. All forms of sensation were lost up to the level of twelfth dorsal and partial loss of pain temperature and touch sensibilities for three segments higher. Routine examinations of the blood and urine gave normal results and the blood Kahn test was negative. Roentgenograms of the lungs revealed no evidence of tuberculosis. Films of the dorsal spine showed a marked scoliosis to the right with maximum angulation at the sixth dorsal (Fig. 2). There was no evidence of other pathology in the spine or ribs.

Fig. 2 A drawing made from a roentgenogram of the dorsal spine in the case of G. S. to illustrate the degree of scoliosis. The maximum angulation is at the sixth dorsal.

In view of the seriousness of the neurological findings it was felt that an exploration of the spinal cord was advisable. On December 9, 1943, the laminae arches from the second dorsal to the seventh dorsal inclusive were removed under avertin anesthesia. No evidence of extradural cyst or neoplasm was disclosed. An incision was made in the dura and a soft rubber catheter was easily passed upward to the seventh cervical and downward to the twelfth dorsal. The cord except for a marked rotation and angulation appeared normal. There was no evidence of bone pathology within the limits of the exploration. It was concluded that the angulation of the cord had been exaggerated rather acutely and that this was the factor responsible for loss of function. It being obvious that the laminectomy had not relieved the deformity, the idea of transplanting the cord seemed logical. To accomplish this, portions of the pedicles and transverse processes of the vertebrae and heads of the ribs at the fourth dorsal to the seventh dorsal inclusive were rongeuired away on the concave side. Four pairs of nerve roots were ligated and severed extradurally from the third to the sixth dorsal inclusive. As soon as the roots were severed, the cord with very little aid assumed its new position so as to relieve the acute angulation (Fig. 2). The wound was closed in the usual manner without further procedure.

The postoperative course was uneventful except for a superficial infection in the wound which healed readily. Within 3 days the patient began to recover sensation and motor function in the lower ex-

trémities. On January 22, 1944, a plaster jacket was applied from shoulders to groins, and on March 17, 1944, he was discharged with almost complete recovery of sensation, motor function and bowel and bladder control. He returned home by train and fully ambulatory.

A follow-up letter from the Public Welfare of New Mexico on March 9, 1946 (3 years following discharge from the hospital) stated that several check-up examinations revealed a continued state of well-being. A recent check by Dr. R. F. Forbis, Hot Springs, New Mexico, revealed no losses in the neurological status and the scoliosis appears to have become quiescent. (In May 1944, a Taylor brace was substituted for the plaster jacket.) The boy is ambulatory without crutches and has been trained in boot making by the State Vocational Rehabilitation Service.

Cord signs associated with scoliosis of this type are rare. The impairment of cord function in this patient was undoubtedly due to a more rapid development of acute angulation than usual. The cause of the scoliosis is undetermined and no other pathology of the spine or cord could be demonstrated. The rapid recovery of function after the acute angulation of the cord was relieved and the patient's course during the past 2 years indicate that there is no other pathology in or about the cord. Laminectomy alone would have afforded no relief, but the results of the cord transplantation show the possibilities of extended

Fig. A drawing illustrating the manner in which the cord was transplanted in the case of G. S. After ligating and cutting the nerve roots extradurally from the third to the sixth dorsals inclusive, the cord was moved into its new position and the acute angulation relieved. The patient presented the neurological deficits of almost complete transverse lesion of the cord before operation. Full recovery was resumed following the operation and has been maintained to the time of writing (2 years).

surgery and pave the way toward a more rational solution of the problem.

THE PROBLEM OF THE TUBERCULOUS SPINE WITH CORD SIGNS

As already pointed out, significant cord impairment is not commonly associated with tuberculous kyphosis but occasionally the syndrome does occur. I had the privilege of studying and operating upon 3 such patients in the clinic of Dr. Arthur Steindler and the conclusions and convictions that were evolved from the study are briefly as follows: (1) In all 3 cases a considerable mass of tuberculous granulation tissue was disclosed intraspinal and extradural. The mass of tissue compressed the cord and was the causal factor for the onset of paralysis. In 2 of the patients the kyphosis was of only moderate grade while in the third it was severe. All 3 patients had had tuberculosis of the spine for a long time but the development of cord signs was relatively acute. The granulation tissue (containing some pus) was situated at the lyphotic angle the locus of maximum intensity of the pathol-

ogy of the spine. (2) The development of a tuberculous abscess or tuberculous granulation tissue intraspinal may occur at any time during the patient's course depending on the quiescence or activity of the tubercle. (3) The progress of cord impairment is ordinarily relatively rapid, measured in days or weeks. (4) Laminectomy is indicated in such cases and should not be postponed unreasonably long. The granulation tissue and pus should be removed or adequately decompressed. Obviously the dura should be opened. It is perhaps best not to drain the wound but if a rubber drain is left in place should be removed in 24 hours. (5) Tetraparesis is not the cause of cord impairment. One can be reasonably certain that an expanding mass is developing intraspinal which should be removed. As a matter of fact these pathological events are well known and there should be no puzzling equivocal arriving at the diagnosis and logical treatment. It is a fact nevertheless that when confronted with a patient who has a severe kyphosis of long standing and thought of as quiescent and who begins to develop signs of cord paralysis, there may be considerable decision relative to the indications for surgery. The problem here is not unlike that of osteomyelitis of the spine associated with extradural abscess in respect to diagnosis and treatment. Paralysis develops in the course of days and unless the cord compression is relieved by laminectomy before paralysis is complete the prognosis for return of function is notoriously poor. Spinal punctures are contraindicated in both the pyogenic and tuberculous infections.

TUBERCULOSIS KYPHOSIS WITH COMPLETE LESION OF LONG STANDING (WITH TRANSPLANTATION OF THE CORD)

A. R., a white male aged 41 years, was admitted to the Presbyterian Hospital, Denver, Colorado, April 16, 1944. He complained of severe pain in the distribution of the eighth, ninth, and tenth nerves. He developed a tuberculous kyphosis in childhood and almost lost the use of his legs at the age of 12. He managed to get about with crutches until the age of 38 when he developed the signs of a complete transverse lesion at D 10.

Examination revealed complete sensory and motor paralysis up to the level of tenth dorsal vertebra.

Fig. 3 A drawing to illustrate the intraspinal findings in case of A. R. After removing the laminar arches of the eighth to the eleventh dorsals inclusive a large tumor like mass of fibrofatty tissue presented extradurally at the apex of the kyphotic angle. It had compressed the cord to about one-sixth its normal size. Note how the kyphosis and collapse of vertebral bodies cause a reversal of the normal angle which nerve roots make with the cord.

voluntary bowel and bladder control. There was a marked gibbus at ninth and tenth dorsal. A roentgenogram of the spine showed an extreme kyphosis with angulation at ninth and tenth dorsal and considerable destruction of these vertebrae. The findings were those of an old Pott's disease with no evidence of recent activity.

I had intended to attempt an alcohol injection of the involved nerves to relieve a traumatic neuritis, but this was abandoned because of the severe deformity and distortion of anatomical landmarks. A laminectomy was decided upon for the purpose of cutting the appropriate nerve roots intraspinally.

On May 1, 1944 the laminar arches from the eighth to the eleventh dorsal inclusive were removed. A thick mass of tough scar tissue presented at the ninth and tenth dorsal segments. It was situated posterior to the dura and compressed the cord to about one-sixth its normal size. The mass consisted of fibrofatty tissue and in my opinion was obviously the end result of tuberculous granulation tissue established in early life (Fig. 3). The nerve roots from the seventh to the eleventh dorsal inclusive and on both sides were ligated and cut extradurally to alleviate pain. By gentle retraction of the cord to one side and then the other the posterior aspects of the vertebral bodies and intervertebral discs were chiseled

Fig. 4 A drawing to illustrate the manner in which the cord was transplanted anteriorly and the acute angulation relieved. The new position of the cord indicated by dotted lines is somewhat exaggerated in the drawing. The maximum shift in position anteriorly was one-quarter inch.

away in such a manner as to relax the acute angulation of the cord (Fig. 4). Recovery of function was not anticipated because of the long standing paralysis but the feasibility and ease of anterior transplantation of the cord was demonstrated. There was no evidence of active pathology and the wound was closed in the usual manner.

The patient was considerably relieved of girdle pain but to the time of writing 22 months since the operation there has been no evidence of return of cord function.

There is no question concerning the cause of the transverse myelitis in this case and had a laminectomy been performed early in life when the cord signs made their first appearance this patient might well be ambulatory. This is the significant lesson to be drawn from the case. There appeared to be two episodes in the patient's history. At about the age of 14 he became partially paralyzed but managed to get about with the aid of crutches. At the age of 38 the paralysis became complete. Judging from the histology of the scar tissue I do not believe there was a recrudescence of active tuberculous pathology. The intraspinal mass of tissue was established early in life and was of considerable size. It is quite likely that some small aggravation of the kyphosis at the age of 38 was sufficient in conjunction with the tumor like mass to complete the transverse lesion of the cord.

EVALUATION OF RESULTS

In respect to the possibility of anterior transplantation of the cord I feel the follow

ing remarks are pertinent (1) I do not feel that the procedure has an application of special importance in the treatment of tuberculous kyphosis with cord signs. The causal factor in these cases has already been elaborated. Moreover in the treatment of active tuberculous infection more harm than good might easily be done in attempting such a procedure. (2) The application of anterior transplantation of the cord may be of value however in other types of cases for example in the case of rapidly developing acute kyphosis following trauma. (3) In performing a number of laminectomies in cases of compression fracture of the spine associated with a transverse cord lesion I have been impressed with some consistent findings. It is often difficult to correlate the benign appearance of the cord at the level of the fracture with its total and permanent loss of function. Macroscopically and to palpation at any rate there often appears to be no anatomical disruption or softening of the cord. There is almost always however an acute hump knuckle or angulation in the cord due to a posterior protrusion of the fractured vertebral body. A simple laminectomy does not correct this deformity. I have strongly entertained the belief that the acute pressure of the bony protuberance that indents the anterior aspect of the cord impairs or obstructs the anterior spinal artery. It may be possible that the resulting vascular insufficiency contributes materially to the transverse myelitis and impairment of cord function. In any case if an emergency laminectomy is performed in the case of acute spinal fracture with transverse myelitis, I feel the significant objective consists in removing the bony or cartilaginous protrusion into the spinal canal. While this is quite possible technically it should be done with great care. Careless re-

traction of an acutely damaged cord obviates all chance of recovery. If one pairs of neighboring nerve roots are first cut extradurally retraction of the cord and chiseling of the protruding vertebral body is greatly simplified. However one has to disturb ever so little the blood supply to a damaged cord segment by severing the vessels that accompany nerve roots. These must be left for future evaluation and to be determined for the individual case. While such treatment of the acute spinal fracture may not be strictly relevant to the cord transplantation it is discussed because the technical procedure is much the same for the latter.

SUMMARY AND CONCLUSIONS

The feasibility and indications for lateral and anterior transplantation of the spinal cord are discussed. A case of severe kyphosis with acute angulation and physiological transverse lesion of the cord is presented. The cause of the scoliosis was undetermined. Lateral transplantation of the cord with relief of the acute angulation resulted in complete resumption of cord function.

The onset of serious cord impairment associated with tuberculous kyphosis should be considered due to an intraspinal tuberculous process or growth of granulation tissue. Laminectomy and decompression of the cord is definitely indicated. A case of tuberculous kyphosis with transverse myelitis is presented. A tumor like mass of scar tissue was disclosed intraspinally at the apex of the kyphotic angle. This was the responsible factor for the complete transverse lesion of the cord and was the result of tuberculous granulation established early in life.

RECONSTRUCTIVE SURGERY OF THE CHEST WALL

KENNETH L. PICKRELL, M.D. HORACE M. BAKER, M.D. and
JOHN P. COLLINS, M.D. Durham, North Carolina

ALTHOUGH thoracic surgery is one of the newest fields of surgical development the results achieved during the past two decades have been remarkable. Significant contributions to this field of surgery have been made by Lilienthal, Sauerbruch, Nissen, Churchill, Cutler, Graham, Alexander, Beck, Blalock, Rienhoff and Blades. The advances made in reconstructive surgery of the chest wall, however, have not paralleled the advances made in intrathoracic surgery. Plastic or reconstructive surgery should by no means be limited to those parts of the body that are exposed. From the standpoint of plastic surgery, there is no essential difference between the repair of defects of the chest wall or the extirpation of a recurrent carcinoma of the chest wall following a radical mastectomy and the covering of an injured eyelid, the closure of a salivary fistula, the removal of a carcinoma or scar of the face, or the re-establishment of motion in a hand distorted as the result of burns. The textbooks on general surgery, however, devote little if any space to reparative surgery of the chest wall, although some operative procedures for the repair of defects in this region may be found in specialized articles (13-16).

There are many conditions of the chest which may not respond well to ordinary procedures but which can be greatly benefited by the application of the more intensive and specialized techniques developed from experience in plastic surgery. The purpose of the present paper is the enumeration and brief description of certain of these conditions and a more detailed account of the procedures employed in the treatment of 3 specific conditions, namely, recurrent carcinoma of the breast, persistent bronchial fistulas, and hypertrophy of the breast.

SURGICAL TREATMENT OF RECURRENT CARCINOMA OF THE BREAST

Few operations have been designed for the eradication of neoplastic processes recurring after the removal of tumors of the breast and chest wall either by surgery or by irradiation. The use of irradiation therapy to supplement surgical excision has prolonged the life of some patients with recurrent cancer of the breast, but many do not receive the benefit of irradiation when the disease has recurred, and only rarely is the surgeon willing to make a second attempt to eradicate the disease. The statements (3) that 'recurrent or metastatic deposits of mammary cancer which make their appearance following radical mastectomy are manifestations of an incurable disease' and that 'the disease cannot be eradicated in this stage by any of the therapeutic measures available at present are fortunately no longer true. Any operation which improves the effectiveness of surgery or irradiation or which prolongs life must be considered of value.

The distinction between recurrent and metastatic cancer is seemingly an arbitrary one. The *recurrent* lesions are those which appear in areas which are easily accessible to operation. The *metastatic* ones appear in more distant organs. Geschickter has found that recurrence is seen in the skin and subcutaneous tissues of the chest wall, in the lymph nodes of the axilla or supraclavicular region on the affected side, and in the opposite breast in this order of frequency. Nodules in the skin of the chest wall, in the parasternal region, are the most common type of skin recurrence following radical mastectomy. Other similar manifestations include recurrence in the scar, isolated nodules in the skin, multiple nodules of carcinoma *en cuirasse* and the carcinoma *tous dermatitis* referred to as inflammatory or erysipeloid cancer.

Major factors influencing the probability of recurrence and determining the technique for

From the Division of Plastic and Maxillofacial Surgery, Duke University School of Medicine and Duke Hospital, Durham, North Carolina.

eradication of the recurrent growth are the type of incision and procedure employed in the initial operation for mastectomy. Numerous modifications of the original Halsted (7) operation have been made by different operators (5 10 14 17 18) independently or inspired by Halsted's work (Fig. 1). Time and experience, however, have led the majority of surgeons to a fuller appreciation of Halsted's (6 8) basic methods and principles. In using the elliptical incision which parallels the anterior axillary fold, the operator may follow either the Halsted or the Handley techniques. That of Halsted, which frequently necessitates grafting, requires the removal of a wide margin of skin around the growth. The Handley technique involves removal of less skin, but more extensive undermining of the flaps in order to secure primary closure. Stewart employs transverse elliptical incisions, which may permit the removal of large amounts of skin and primary closure without grafting (Fig. 1).

Whatever the type of radical mastectomy preferred by the surgeon, an attempt is made at operation to remove in one mass all of the structures which are liable to immediate invasion by the tumor. Because of the assumption that spread of the disease from its original focus proceeds by continuous permeation in all directions, an extremely wide excision *en bloc* of the structures surrounding the primary tumor is advisable. Separation of the tissues by any means within the operative field must be scrupulously avoided, for such separation may result in the invasion of structures by tumor being left behind. Halsted's original basis for the operation was empirical and antedated Handley's theory of lymphatic permeation by cancer cells. However, Halsted's experience with the localization of recurrences and metastatic foci following less extensive types of mastectomy is ample reason to attempt the widest possible excision.

It is true that in some cases the extension of the cancer occurs by way of the blood stream and that tumor emboli may result in distant metastases even though the microscopic examination of the specimen following radical mastectomy fails to show involvement of the axillary lymph nodes and neighboring structures. Nevertheless, the operation is

performed by Halsted (7) and Meyer remains the standard procedure for radical mastectomy since it is based on sound surgical and pathological principles and is applicable to the majority of cases in which clinical evidence fails to indicate that the disease has already passed beyond the scope of operability. The proximity of the cancer to vital structures and its extent at the time of operation greatly influence the success of treatment.

Geschickter states that the 5 year survival rate in surgery in operable cancer approximates 70 per cent for cases without axillary involvement and 25 per cent in cases with axillary involvement. The two groups are about equal in size. The combined curability averages 47 per cent. Adair found that the 5 year survival rate for radical mastectomy in the operable group was 45 per cent and only 18 per cent in a similar group treated by excision alone.

The criteria for inoperability should not influence the surgeon to exclude operation for palliative reasons, in cases in which radiation is inadequate or contraindicated, nor should it be assumed that all of these patients are definitely incurable, as was the assumption in the cases here presented (Figs. 2 6).

CASE 1. A 44 year old white woman was admitted to the Duke Hospital May 10, 1945. Ten years previously a mass had developed in the left breast which was excised at another hospital. It promptly recurred and a radical mastectomy was performed by a second surgeon. During the ensuing year, she received intermittent irradiation therapy following which she remained asymptomatic for 5 years, when the lesion recurred in the chest wall. A biopsy taken and histologic sections disclosed a "recurrent medullary carcinoma." The lesion was considered "inoperable" and palliative irradiation was instituted. The patient was given a total of 2100 roentgen units to the primary recurrence with the use of 500 kilovolts, 30 centimeters distance, 0.25 tin filter. Three months later this same area was given 1200 roentgen units with 500 kilovolts, 30 centimeters distance, 0.5 copper filter with the lesion well shielded. The patient returned 18 months later with numerous areas of recurrence in the skin of the chest wall each of which was treated separately by superficial therapy. She was also given 1200 roentgen units to a sterilization dose. The lesions which they recurred 1 year later she could not be treated with additional irradiation, whereas she was admitted to the hospital for operation. She recurred with carcinoma of the breast and secondary lesions.

Fig. 1 The major factors which influence the probability of local recurrence are the type of incision and procedure employed in the original operation for mastectomy. Numerous modifications of the original Halsted incision have

been made by different operators (5, 10, 14, 17, 18). Whatever the type of incision employed, an attempt should be made to remove *en bloc* all of the structures which are liable to immediate invasion by the tumor.

(Fig. 2a) An exposed rib could be seen at the base of the ulcer. The surrounding skin was thin and telangiectatic. Pain was constant and intractable.

Operation. Excision of recurrent carcinoma of the chest wall: application of split thickness skin grafts to pericardium. On May 12, 1945, with the patient anesthetized with sodium pentothal and nitrous oxide, a closed system being used, the entire chest, abdomen, and one thigh were prepared as a sterile field. The proposed area of excision was widely outlined by a toothpick moistened with 5 per cent alcoholic solution of brilliant green. The medial incision extended along the right lateral border of the sternum. The superior limb followed the clavicle high into the axilla (Fig. 3). The inferior incision began along the right costal margin and traversed the left costal margin. The lateral incision followed the medial margin of the latissimus dorsi. The recurrent carcinoma and the soft tissues of the entire left chest wall were removed *en bloc*, beginning at the periphery. The tumor had invaded the underlying ribs and parts of the sternum together with the third, fourth, fifth, sixth, and seventh ribs were resected and the pericardium was exposed (Fig. 3). There were no visible implants in the pleura.

The very large operative defect was reduced somewhat in size by approximating the four corners (Fig.

5). It was impossible to cover the defect with a direct transfer flap or to utilize the right breast, which was quite small. There was no alternative other than to tack the pericardium to the intercostal muscles and sternum (Fig. 4) by interrupted sutures of white silk. Although the heart was seemingly lifted forward by this tacking procedure, there was no visible interference with its function. Two large heavy split thickness skin grafts cut from the thigh were sutured to cover the operative defect which measured 8 inches wide (19.6 cm.) and 9 inches long (19.8 cm.) (Fig. 5). The suture ends were not cut so that they could be tied over a bolus of cotton waste to obtain pressure on the graft directly over the pericardium. The operative area was dressed 10 days later at which time there was an almost complete take of the graft except for a 2 centimeter area over a protruding portion of a resected rib which did not completely heal for several weeks. The patient at present (Fig. 2b, c, d) is entirely well and performs her household duties without symptoms. She does not wear a protective support. The electrocardiogram is normal and no murmurs are heard over the heart. There is no evidence of local recurrence or distant metastases.

The graft has remained soft and semitransparent. Cardiac contractions and pulsations are clearly visible. Forced expiration with increased intrapulmo-

Fig. 3. Case 1. a, A large recurrent carcinoma of the chest wall following radical mastectomy and irradiation therapy. Her condition was thought to be inoperable. She could not tolerate additional irradiation. b, Lesion widely excised together with underlying ribs and sternum and split skin grafts applied directly to pericardium and chest wall. c, Position of graft at forced expiration. d, Graft-covered pericardium is drawn inward at beginning of inspiration. Photographs b, c, d were taken 18 months following operation.

nary pressure causes the graft covered pericardium to bulge beyond the surrounding chest wall (Fig. 3c). When the patient decreases her intrapulmonary pressure the graft covered pericardium is drawn inward below the level of the chest wall (Fig. 3d). Violent waves are seen when the patient coughs.

So far as we are aware this is the first time that a skin graft has been applied directly to the pericardium.

CASE 2. A 45 year old colored woman was admitted to the Duke Hospital January 6, 1951. Five months previously she noted a mass in the left breast which continued to increase progressively in size. She had lost about 20 pounds in weight and had scanty menstrual periods followed the birth of her last child 2 years previously.

Physical examination showed a hard, slightly tender, freely movable mass measuring 3 by 5 centimeters located in the upper inner quadrant of the

Fig. 3

Fig. 3. The recurrent carcinoma was widely excised. The tumor had invaded the underlying ribs, and parts of the sternum together with the third, fourth, fifth, sixth, and seventh ribs were resected and the pericardium and left pleural cavity exposed.

Fig. 4. The pericardium was tacked to the intercostal muscles and fascia covering the sternum, by using interrupted sutures of white silk so as to form a surface on

Fig. 5

which a graft could be placed. Although the heart was lifted forward by this tenting procedure, there was no visible interference with its function.

Fig. 5. The large operative defect of the chest wall was somewhat reduced in size by approximating the corners. Two heavy split thickness skin grafts cut from the thigh were used to cover the defect which measured 8 inches in width and 9 inches in length.

left breast. Although several axillary lymph nodes were palpable they were not interpreted as metastases. She had hypertensive cardiovascular disease. The blood pressure was 200 systolic and 140 diastolic. A roentgenogram showed the heart to be moderately enlarged. The aorta was tortuous. There was a harsh blowing aortic murmur heard over the entire precordium. Serologic tests for syphilis were strongly positive.

A radical mastectomy was performed by use of a wide en bloc excision. Since the skin flaps could be approximated a skin graft was not used. Pathologic sections disclosed an adenocarcinoma of the breast without axillary metastases. During the convalescence she received 2000 roentgen units of irradiation through two ports.

She remained well for almost 1 year. Upon returning for a checkup examination on January 4, 1946 she was found to have a hard fixed neoplastic mass in the skin and sternum overlying the junctions of the second and third ribs on the left side (Figs. 6a, b). A roentgenogram of the chest showed the heart to be tremendously enlarged in its transverse diameter. No destruction of the sternum or ribs was discernible.

Operation. On January 6, 1946 with the patient anesthetized with ether a closed system being used an incision was made to encircle widely the recurrent carcinoma. The medial parts of the second and third ribs, together with the left lateral margin of the sternum and manubrium were resected. The pleura was opened. The great vessels at the base of the

heart appeared normal. No pleural implants could be felt.

The remaining breast was thin and pendulous (Fig. 6a) and could be readily mobilized upward. A direct transfer single pedicle flap was measured and outlined with brilliant green (Fig. 7). It was then incised, transposed and sutured to cover the operative defect, two rows of interrupted sutures of silk being used. The area from which the flap was taken was closed in a similar manner by drawing the breast upward (Fig. 8). Pathologic sections disclosed a recurrent adenocarcinoma of the sternum and ribs. All incisions healed *per primam* and the patient was discharged on the tenth postoperative day (Fig. 6c).

PRIMARY TUMORS ARISING IN THE CHEST WALL

Many of the common *benign tumors* have been found to arise in the chest wall. The most important however are those which arise from the bones. Simple osteomas have been described but in many instances cartilage is present and therefore these tumors should be classified as enchondromas. Some are malignant and this is particularly true of the cartilaginous tumors which arise in the costal cartilages or the scapula. They may become tremendous in size even when they are benign and may produce pressure against

Fig. 6. Case . . . a, b Recurrent carcinoma of the sternum, manubrium, and ribs following radical mastectomy performed . . . year previously. c, Recurrence . . . as excised

and defect covered immediately with direct transfer single pedicle flap from the opposite chest. All photographs taken on 14th postoperative day.

other structures. On other occasions, marked deformities develop. Extirpation of these tumors should never be undertaken lightly, for one may have to remove a large portion of the chest wall (Fig. 9). The most common malignant tumor arising in the chest wall is a *sarcoma*, practically all varieties of which have been observed in this location by Hedblom. In a series of 213 cases of tumors of the bone

chest wall Hedblom found 131 to be sarcoma.

Carcinomas of the chest wall, exclusive of those which arise in the mammary gland, in the skin, or in the axilla, are never primary. (4)

OBLITERATION OF EMPYEMA CAVITIES CLOSURE OF BRONCHIAL FISTULAE

Empyema. The primary object in the treatment of acute empyema is first to save the life

Fig. 7. The recurrent carcinoma was removed by resecting parts of the manubrium sterni, second and third ribs. The great vessels at the base of the heart were exposed. A flap from the right breast was outlined with brilliant green.

Fig. 8. A direct transfer single pedicle flap from the neck upper chest wall was transposed and sutured in position to cover the operative defect, two rows of interrupted sutures being used. By drawing the right breast upward, the donor area could be closed.

Fig. 9. A 36 year old white man with a sarcoma of the posterior chest wall which had grown from a walnut-sized mass to its present dimensions in 2 years. a, b) Repeated hemorrhages from the tumor hastened his admission to the

hospital. X-ray films showed no destruction of the spine or ribs. The tumor was widely excised and the defect covered with two heavy split skin grafts. c, Photograph on sixth postoperative day—sutures not yet removed.

of the patient and second to prevent chronicity. A frequent cause of chronic empyema is failure to provide adequate drainage. Other contributing factors are the presence of foreign bodies or cavities which cannot be obliterated because of fibrosis of the lung and fixation of the mediastinum or the rigidity of the overlying chest wall preventing approximation with the lung or conversely by the rigidity of the lung. Many of the operations designed for the correction and treatment of chronic empyema are based on the principle of freeing the rigid walls of the cavity to permit approximation of the tissues and healing by the formation of scar tissue. The Estlander operation involves removal of the overlying ribs—a procedure not always adequate since the underlying parietal pleura may be so greatly thickened that collapse of the chest wall will not occur unless the pleura is also removed. The Schede operation is designed for removal of the thickened parietal pleura. The principle of the Delorme operation is the removal of the rigid surface of the visceral pleura from the lung in order to permit it to expand enough to contribute to obliteration of the cavity.

Bronchial fistulas frequently follow operations for empyema or lung abscess as residual communications between the bronchus and the skin. While serious hemorrhages may occur from the mouth of the fistula the chief complaint of the patient is the inconvenience caused by wearing a dressing. Of greater importance is the serious danger of immersion of

the fistula in water which may result in drowning by the entrance of water directly into the lungs through the external opening.

There is a tendency for all especially the smaller bronchial fistulas to heal as the result of circular contraction of the peribronchial tissue and of the scar tissue around the mouth of the fistula shown experimentally by Bettman, James Tannenbaum and Slobe. Consequently a period of several months should elapse before operative closure is undertaken. However if a large bronchial opening becomes adherent to the skin it is less likely to close spontaneously than if it were deeply situated and in some instances the fistula persists. Graham and Blades have found that repeated cauterizations of the bronchial fistula are usually ineffective. Some fistulas may be closed with several rows of sutures after the lung has been freed from its attachments to the chest wall—a procedure which will permit the contraction of scar tissue to aid in the closure.

In many instances more extensive reconstructive procedures occasionally involving partial resection of the lung are necessary for the permanent closure of the fistulas. When the decision has been made to close a fistula surgically the operation should be preceded by attempts to determine the size, extent and contour of the fistula and the presence or absence of a foreign body. Since the transposition of a skin, or skin and muscle flap is a simple procedure it would seem that this is the method of choice especially when the bron-

Fig. Case 3. a, b, c Deformity of the chest wall resulting from two operative procedures to drain an empyema and lung abscess, and from four subsequent operations performed to close the persistent bronchial fistula. A communication with the bronchus can best be seen in b. A pectoral muscle flap was transposed to fill the defect. Condition prior to discharge, c, d, taken on the eleventh postoperative day.

chial fistula leads into a pulmonary cavity of considerable size. The success encountered by this means in the elimination of long standing bronchial fistulas resistant to lesser procedures is illustrated in the following case.

CASE 3. A 24 year old white man was admitted to the hospital January 15 1945. He had had pneu-

monia in 1936 1937 1938 and, then first seen on February 25, 1941. He had the signs, symptoms and findings of a large empyema on the right. The anterior portions of the fifth and sixth ribs were resected to establish open drainage and, subsequently parts of the fourth and seventh ribs were removed to drain a large lung abscess. During the following months, the patient developed multiple bronchial fistulas which persisted even though the

Fig. 11. Insert shows the horse-shoe shaped incisions used to excise the scars resulting from the previous operations. The large skin and subcutaneous tissue flap was mobilized superiorly to the clavicle. The pectoralis major was incised beginning about 3 centimeters above the superior border of the pulmonary cavity and continued upward as shown by dotted line, along the right lateral border of the sternum and the clavicular attachment was freed superiorly.

Additional operations were performed in 3 years in an attempt to close them. Hemorrhage from the mouth of the cavity hastened the present admission.

The right chest wall was markedly deformed due to previous operations, the chronic empyema, and the bronchial fistulas (Fig. 10a, b, c). He had to wear a dressing constantly. He could not take a tub bath or go swimming for fear of drowning, and when

Fig. 13. The pectoral muscle flap was transposed laterally and inferiorly in order to obtain the necessary length to cover completely and reinforce the first line of sutures. The flap was then anchored in its new position to the originally incised inferior muscle margin. The heavy skin and subcutaneous tissue flap was then sutured to the inferior incised margin with interrupted sutures of silk.

smoking it was embarrassing to him and disconcerting to others to see the smoke curl from beneath his clothing.

On January 19, 1945 the following operation was carried out under pentothal nitrous oxide-ether anesthesia. The scars resulting from the previous operations were removed by using horse-shoe shaped elliptical incisions as shown in the insert (Fig. 11)

Fig. 12. The muscle was incised about 3 centimeters above and below the margins of the pulmonary cavity a. The muscle flaps were mobilized toward each other and sutured with interrupted silk, b.

Fig. 14. Gravid hypertrophy of the breasts occurring in a year old colored woman. Although there was some increase in size associated with the progression of pregnancy it was not until she had reached the seventh month that her breasts began to increase rapidly in size, and within 3 to 4 weeks had assumed tremendous proportions. The breasts did not regress during the postpartum period. The patient, as almost completely incapacitated, any movement was laborious and awkward. A right mastopexy was performed. The specimen weighed 3 pounds (1.4 kilos). Since it was not advisable to transpose the nipple nor to use it as a free graft, an artificial nipple and areola were constructed.

A large heavy pectoral skin and subcutaneous tissue flap was elevated superiorly and the inferior border was undermined and mobilized (Fig. 15). The pectoralis major was incised about 3 centimeters above

and 3 centimeters below the borders of the primary cavity (Fig. 15a). These flaps were mobilized and then turned inward and sutured with interrupted sutures of silk partially to obliterate the

cavity (Fig 12b). A pectoral muscle flap was then elevated by incising the muscle along the lateral margin of the sternum medially and the clavicular attachment was freed superiorly (Fig 12). The entire muscle flap was mobilized and rotated laterally and inferiorly to obtain the necessary length to cover completely and reinforce the first line of sutures. The flap was then anchored in its new position to the originally incised inferior muscle margin (Fig 13). Interrupted sutures of silk were used. The heavy skin flap was treated in a similar manner. No drains were inserted. Primary healing occurred and the patient was discharged 12 days after the operation. He has remained entirely well.

RECONSTRUCTIVE SURGERY OF HYPERTROPHIED PENDULOUS BREASTS

Benign and malignant breast tumors have at least one feature in common: they are formed by abnormal and purposeless multiplication of cells previously derived from normal cells. Benign tumors resemble closely the tissue from which they originate. The cells are arranged in a relatively orderly fashion and although the tumor may attain great size it rarely jeopardizes the life of the host except by interference with vital functions by pressure. In contrast, malignant neoplasms consist of abnormal cells which may tend to approach the undifferentiated embryonic type. They are not orderly in growth but invade and destroy adjacent tissues or metastasize to distant parts of the body and finally lead to the death of the patient.

Massive hypertrophied breasts are in most instances comparable to benign tumors and should be considered and treated as such. The increased size may be due to enormous deposits of fat or to marked proliferation hyperplasia, and hypertrophy of the breast tissue proper (Fig 14). Massive breasts not only incapacitate the bearer but are conspicuous and unsightly. The breasts cause self-consciousness in the bearer, are a source of pain and discomfort, and may cause scoliosis, kyphosis or lordosis. The excessive perspiration is unpleasant, and the patients avoid society, become depressed and morose and an ensuing psychosis may develop.

Surgical removal or correction of hypertrophied breasts is just as real and as fully justifiable especially in young women as the indication for many ordinary or well recognized surgical procedures such as the correc-

tion of gynecomastia in the male or the reduction in size of an elephantoid extremity due to lymphatic obstruction. Rather than simply to amputate such breasts, it is much better to remove them in a manner that leaves a pleasing instead of an ugly appearance at their site if this can be accomplished without increase in the risk. Reconstruction of enlarged breasts is indicated when the hypertrophy leads to a disfiguring or disabling deformity and when there is a reasonable probability that the operation will restore the affected parts approximately to normal without undue danger to the patient. The operation is designed to restore physical as well as psychological balance and properly executed it will accomplish these objectives.

In the technique for the correction of massive breasts by partial removal, there are many variations in procedures and many details helpful in obtaining the desired final result. Some of these have been described by Thorek, Maliniac, Lamont, Pickrell, and others. In some instances satisfactory results in the treatment of massive hypertrophy of the breasts can be attained only by subtotal excision of the enlarged organs and construction of an artificial nipple (Fig 14).

Virginal and gravid hypertrophy. While the majority of cases of virginal hypertrophy have their onset during adolescence, a similar condition may also occur during pregnancy. Virginal hypertrophy must be distinguished from adipose breasts. Enlargement of the breasts due to deposition of fat may occur in cases of pituitary disturbance where there is an increase of fat about the hips and in the mammary glands but the excessive growth seen in virginal hypertrophy does not occur.

"Because the end-organ rather than the hormonal functions is at fault in virginal and gravid hypertrophy, endocrine therapy is unsuccessful." (3) Surgery therefore is the only alternative.

CONCLUSION

There are many conditions of the chest wall which can be greatly benefited by the application of specialized plastic surgical techniques. While the foregoing presentation is selective, we have briefly described the procedures em-

ployed in the treatment of four specific conditions, namely (1) recurrent carcinoma of the breast (2) sarcoma of the chest wall, (3) persistent bronchial fistula, and (4) hypertrophy of the breast

A case is presented in which a skin graft was used successfully to cover the pericardium following excision of a recurrent carcinoma of the chest wall.

PROTECTIVE ACTION OF SULFANILAMIDE ON EXPERIMENTAL CHLOROFORM HEPATITIS

CARLOS A. TANTURI, J. A. LONCHARICH and R. F. BANFI, Buenos Aires, Argentina

DIFFERENT substances exist which exert or display a protective action against experimental chloroform intoxication. Methionine and cysteine decrease the degree of hepatic injury and the mortality rate produced by chloroform in hypoproteinemic dogs (10). Xanthine and sodium ricinoleate increase the resistance of rats against the toxic action of carbon tetrachloride and chloroform (7). The same investigators found that sulfanilamide given orally to rats protects them against the chronic carbon tetrachloride intoxication as measured by the degree of liver cirrhosis and the mor-

tality rate. The protective action is shown by the mild liver necrosis always observed in the sulfanilamide fed rats as compared with the controls. The protection seems to be due to the sulfonamide group. *p*-amino benzoic acid does not interfere with the protective action exerted by sulfanilamide.

Forbes and Evans (5) studied the action of sulfanilamide against the liver injury produced by chloroform inhalation in rats. They classified results according to the degree of liver central necrosis revealed on the histologic examination.

After an extensive study we found that chloroform anesthesia of 1 hour's duration in dogs produces a hepatic lesion (hyaline central necrosis) which is followed after 3 weeks, by a

complete histological recovery of the parenchyma, although regeneration by rapid multiplication of the remaining hepatic cells replaces the greater part of the functional deficit of the organ within 6 days (3, 4). In these instances hypoprothrombinemia is an early index of the hepatic damage produced by chloroform. The lowest values are obtained 24 to 48 hours following anesthesia. By the fifth day (or at most the sixth) the prothrombinemia has reverted to its normal value. Its variations closely indicate the course of injury as well as the reactive capacity of the liver (12).

In the present work we have studied the protective action of sulfanilamide on liver injury produced by chloroform anesthesia in dogs as well as the degree of hepatic insufficiency and protection by sulfanilamide as measured by the variations in prothrombinemia as compared with controls.

METHODS

Two groups of normal dogs which had been fasted for 3 days (water ad libitum) were used.

One group received orally 150 milligrams of sulfanilamide per kilogram of body weight daily during 5 days prior to the anesthesia. The other group served as a control. Each pair of dogs (sulfanilamide and control) was subjected at the same time to chloroform anesthesia of 1 hour's duration. A Bock apparatus was used in order to minimize the variations imputable to the anesthesia itself. The blood concentration of sulfanilamide was determined periodically during the period of treatment and after the anesthesia by the method of Banfi and Loonchanch (2). The variations of prothrombinemia were followed in the same samples of blood drawn during the experimental period. The method of Tamm and Banfi was used for the last purpose (11).

RESULTS

In Table I are shown the results obtained in 8 control dogs subjected to a chloroform anesthesia. 5 died within 24 to 48 hours after the anesthesia. All dogs previously fed with sulfanilamide survived. The decrease in prothrombinemia was less pronounced in the

Fig. 3. Dog 517 (sulfanilamide). a, left, Biopsy of liver. Low power view 48 hours after anesthesia. Very mild injury. b, High power showing no nuclear derangement and almost normal architecture.

binemia produced by chloroform was less in the sulfanilamide group than in the controls.

The degree of protection is expressed by the difference between the lowest concentrations of prothrombin reached after the anesthesia in the sulfanilamide fed dog and in the control. The protective index thus obtained gives a fairly approximate figure of the protection conferred. In every instance the favorable influence exerted by sulfanilamide is shown. The protective index varies from +6.4 to +79.5 averaging +35. This average was calculated by excluding the results obtained in the pair of dogs 611 and 614 because in this instance sulfanilamide was administered 1 hour prior to the anesthesia. If sulfanilamide is given 1 hour prior or during the anesthesia, the drug does not exert any protective action.

The effect exerted by sulfanilamide is shown during the first 24 hour period after the anesthesia. During this period the control dogs regularly vomit and are depressed. These symptoms were not observed in the sulfanilamide group. The photomicrographs show

pieces of liver tissue obtained 48 hours after the anesthesia. The degree of hepatic necrosis was less in the sulfanilamide treated group if compared with the control.

COMMENT

The results obtained clearly show that sulfanilamide exerts a protective action against liver injury produced by chloroform in dogs. The degree of liver injury, its course, the reactive capacity and the protection conferred can be accurately measured following the variations in prothrombinemia. When sulfanilamide is administered at the same time or 1 hour prior to the anesthesia, the protective action is not observed, which suggests that the action displayed by the sulfanilamide is not a direct one through the liver parenchyma. McIver (9) has shown that thyroxine increases the susceptibility of rats to chloroform intoxication. Earlier works on chloroform liver injury in dogs also pointed out the increased susceptibility to chloroform of the animals previously fed with thyroxine. Several investigators (1-8) showed that sulfanilamide de-

presses the basal metabolic rate in rats by producing an increase in size of the thyroid gland and decrease of colloid. From these studies Forbes presumes that the action of sulfanilamide in protecting the liver against the chloroform injury is due to the decreased susceptibility, obtained through a thyroid depressing effect of sulfanilamide. If the same hypothesis is to be used to explain the results obtained in dogs, it must be submitted to experimental investigation.

Many clinical cases of liver necrosis due to sulfanilamide were reported in the literature. However, some authors recommend the use of the drug in biliary infection. To the present time no experimental animal is suitable for producing a liver injury with sulfa drugs. We were not able to produce a liver injury with any dose of sulfanilamide in dogs. This leads us to presume that human susceptibility to sulfa drugs stands by itself. Therefore the mechanism by which the protective action of sulfanilamide is exerted against chloroform liver injury in dogs would explain many of the contradictory findings found in the literature concerning the toxic action of sulfanilamide on human liver. Further investigations are required.

CONCLUSIONS

1 Sulfanilamide given daily to dogs prior to a chloroform anesthesia of 1 hour's duration

decreases the degree of liver injury regularly produced by chloroform. In this experimental condition hypoprothrombinemia and histological changes are less severe than in the control animals.

2 The degree of protection obtained with sulfanilamide can be accurately expressed by the protective index which results from the difference between the lowest figures of prothrombinemia obtained in the sulfanilamide-fed dog and the control.

3 Sulfanilamide given to dogs during the time of the anesthesia does not protect against liver injury produced by chloroform.

GASTRIC CARCINOMA

A Comparative Review of the Origin, Diagnosis and End-Results in 583 Patients

ROBERT H. ABRAHAMSON M.D. F.A.C.S. Stamford Connecticut and
J. WILLIAM HINTON M.D. F.A.C.S. New York, New York

AFTER the third decade, neoplasm is second only to cardiovascular disease as a cause of death. Since about one-fifth of this mortality is due to carcinoma of the stomach, the subject is of prime importance and worthy of constant repeated analytical study.

In a review covering 444 patients with carcinoma of the stomach discharged from the Fourth Medical and Surgical Division of Bellevue between 1919 and 1938 the dismal outlook was pointed out.⁽²⁾ The purpose of this review is to investigate whether the past 7 years has altered the status of the patient with gastric carcinoma. From 1939 through 1945 of 171 patients discharged with the diagnosis of carcinoma of the stomach, 32 were eliminated because of insufficient diagnostic proof.

The diagnosis in the remaining 139 cases was verified by pathological specimen and unquestionable x-ray evidence. Of these (Fig. 1) 76 (64.3%) were considered inoperable following admission. The reasons for inoperability were: 14 were moribund, 22 had extreme cachexia or senility, 28 showed extensive lesions with metastases, and 12 refused operation. Forty-three per cent of these patients died while on the wards.¹

The remaining 51 cases (36.7%) were considered operable. An effort was made to do an exploratory operation in every case in which any hope for improvement by surgical intervention was thought possible. Exploratory laparotomy in 22 cases (15.5%) proved that no further operative measure could be undertaken. On 10 patients a palliative procedure was performed as temporary relief for obstructive lesions.

In only 19 patients was gastric resection feasible. Whenever possible wide resection was performed even though evidence of significant extension, such as enlarged lymph nodes (which were probably neoplastic) was present. This group had a mortality of 15.8 per cent. Resection was possible in 13.7 per cent of the total number of cases and in approximately 38 per cent of the operable cases. Only 7 patients (5%) were discharged from the hospital as possible cures.

The symptoms in our present series were approximately the same as those found in our previous series of patients. Pain, weight loss, vomiting and weakness were the predominant reasons for seeking medical attention and hospitalization. In an effort to further evaluate the disease, we have attempted to divide the time of the onset of the various symptoms (Table I) into "early" and "late." Pain and loss of weight head the list of complaints, while cachexia and a palpable mass are the common late findings. The value of this compilation is questionable in that the signs and symptoms which are common to one patient are late for another. It is probable that it will be necessary to find additional means and methods other than these symptoms if we are ever to diagnose gastric carcinoma early.

This conclusion is further borne out by a study of the relationship between the time of onset of the signs and symptoms, the operability of the disease, and the resectability of our patients (Table II).

As was also shown in our previous series, the graphic representation (Fig. 2) of the age relationship between operability and the lapse of time after the patient's first complaint does not indicate the possibility of cure. Resectability can be prognosticated by what we now

¹For purposes of this study it is considered a mortality if the patient does not leave the hospital, regardless of the cause of death or length of time following operation.

*Signs and symptoms due to metastases or extension of malignancy (melena, ascites, etc.) have not been listed.

symptomatology. In the overwhelming majority of cases, our present criteria allow us to make a diagnosis only in the late cases and as we continue to depend on inadequate methods, it is only by purest accident that early cases come to operation. Since waiting for clinical signs and symptoms to appear has resulted in low rates of operability and resectability regardless of their duration further attempts to increase our diagnostic accuracy dependent on complaints of the patient are doomed to failure.

GASTRIC ANALYSIS

Gastric analysis was performed in 63 cases. Fifty-five (87%) showed marked hypoacidity or achlorhydria. 6 (8%) showed normal acidity and 2 (3%) showed hyperacidity. In view of the frequency of hypoacidity in normal people over 50 years of age the findings in this test are not diagnostic; however a decrease or an absence of free hydrochloric acid must arouse strong suspicion and necessitates the positive exclusion of carcinoma. The possibility of cancer occurring in the presence of normal and increased acidity has been called to our attention. The high percentage of cases of hypoacidity or achlorhydria in both of our studies is perhaps indicative of the number of patients with advanced type of cancer admitted to Bellevue Hospital. In consideration of the simplicity of this procedure gastric analysis should be part of a routine examination of all those in the cancer age group.

X RAY EXAMINATION

X ray examination of the stomach with contrast media was carried out in 124 of the 139 cases. One hundred twelve showed roentgenologic evidence of gastric malignancy; a diagnostic accuracy of more than 90 per cent. Of the 12 cases eventually diagnosed as carcinoma by autopsy or laparotomy 7 were reported as negative, 3 were diagnosed as ulcer of the stomach, 1 as an extragastric tumor and 1 as a benign tumor of the stomach.

During the 7 years covering our present study there has been a large increase (approximately 30%) in the number of patients subjected to x ray examination for gastric disease. An increasing percentage of cases are correctly diagnosed by fluoroscopic and x-ray examination. The roentgenologist has proved himself vastly superior to the clinician in diagnosis, and the asymptomatic patient will only come to operation subsequent to discovery of the condition by x ray examination (9).

A comparison of the percentage (Fig. 3) of operable cases and the possibility of cure during the past 7 years (Series A) with the previous 20 years (Series B) shows a decided similarity. With the exception of the increase in resectability (2% to 5%) there is no statistically important change. The rate of operability remains approximately the same (33-4% to 36.7%).

Without any attempt to excuse our poor results, it must be considered that the cases studied were of consecutive admissions, and many had been diagnosed elsewhere. Thirty-nine (28%) were considered unresectable by previous laparotomy or clinical examination, prior to admission to the hospital. If this number is subtracted from our total, it raises the percentage of operability from 36.7 to approximately 50 per cent and the percentage of resectability from 13.7 to 19 per cent. Even this increase in the percentage of operable and resectable cases, as compared with the results of our previous series (Series B) should not lead to the conclusion that the status of these patients has changed. The supposed improvement is more apparent than real. It cannot be considered as due to earlier diagnosis or therapeutic advance in view of the end results. In our opinion any increase in oper-

Fig. 1. The results in 139 consecutive cases diagnosed as carcinoma of the stomach from 1939 to 1945. Series B.

ability and decrease in mortality is due to improved techniques utilized in preoperative and postoperative care (i.e. intravenous plasma proteins, amino acids, vitamins, frequent transfusions, Wangenstein drainage, etc.). The institution of an anesthesia service at Bellevue Hospital, with trained anesthetists who visit the patients both preoperatively and postoperatively (frequently using positive pressure paravertebral block, cyclopropane and curare) has decreased the number of post-anesthetic and postoperative complications.

Although an increased number of patients recover from the operative procedure, this in-

crease is not reflected in the percentage of actual cures. This fact is emphasized by a study in the Fourth Division at Bellevue Hospital. 52 patients with a previous diagnosis of carcinoma of the stomach who were readmitted subsequently and observed during this period (1939 to 1945).

Of these 52 patients, 42 were previously operable; exploratory only was performed on 15, palliative procedures on 2, and gastric resections were done on 25. All of these patients either died during their readmission to Bellevue Hospital or they were transferred, by arrangement, to a home for incurables where the

succumbed. None of the patients on whom resection was not done lived longer than 10 months, and the average length of life was 6¾ months. The subsequent course of the 25 patients resected (Table IV) and later readmitted indicates that even though an increase in the percentage of resectability has taken place the eventual outlook for what we now consider the most favorable cases is bad indeed. A life expectancy of less than 2 years following resection cannot be considered progress in the cure of gastric cancer.

PEPTIC ULCERS

There were 16 cases (11.5% of the total) in which the history made the possibility of malignant degeneration of a benign peptic ulcer a factor for consideration. As in the previous series, in which 17.1 per cent of the patients presented this possibility (as well as in other studies 2, 3, 8, 16, 17, 18) these cases have been carefully investigated. Seven were diagnosed as duodenal ulcers, and as such can either indicate errors in diagnosis or the con-

Method. A Levin tube No. 8 was passed through the nose into the stomach, and fasting specimens of about 30 cc. were collected and labeled serially. A 1% solution of barium was injected subcutaneously. A test specimen of about 10 cc. was then taken and labeled No. 1, and after that as many separate intervals additional specimens, the total of which were analyzed and labeled No. 2, No. 3, and No. 4, respectively.

comitant existence of a duodenal ulcer and a gastric malignancy near the pylorus. Each of the 9 cases which were diagnosed as gastric ulcer has been reviewed and received exhaustive study. Since the previous report from our gastroenterological clinic (18) concerning the possibility of malignant degeneration of peptic ulcers, we have followed 165 cases of gastric ulcers over periods from 1 to 19 years, and have failed to find a single case in which the transformation from a benign ulcer to a gastric neoplasm could be proved. Extensive investigations have either shown the separate and individual inception of the lesions, or demonstrated the error in the diagnosis of a benign peptic ulcer for what was later proved to have been a malignant lesion from its onset. In several cases of carcinoma of the stomach which we have reviewed, clinical history or x-ray study caused suspicion that they had their origins in peptic ulceration.

CASE 1. A 60 year old white male in whom a diagnosis of peptic ulcer had been made 17 years before had had a gastric resection at that time. The patient was admitted to this hospital in February 1937 because of a recurrence of ulcer symptoms. A gastroscopic examination revealed two ulcerative lesions near the ostia. He was discharged following improvement under medical care. In June, 1938 he returned because of persistent epigastric pain. An exploratory operation was performed demonstrating disease by gross examination. Gastroscopic examination in December 1938 revealed no signs of ulceration, but the development of atrophic gastritis. He was readmitted in 1943 and laparotomy revealed an inoperable malignant lesion of the stomach.

CASE 2. A 47 year old white male, who had had a resection for gastric ulcer in April, 1930, returned because of malfunction of the stomach in March, 1940. A further gastric resection to eliminate the malfunctioning stoma was performed. Three months later he returned to the hospital because of a recurrence of gastric dysfunction. Exploration revealed extensive stony hard lesions on the stomach, liver peritoneum, and omentum. The pathologist reported carci-

ABRAHAMSON HINTON GASTRIC CARCINOMA

Fig. 3 The relationship of the duration of symptoms to the operability and resectability as indicated by percentages.

noma. At this time the microscopic sections taken from the stomach at the two previous operative procedures performed in 1937 and 1940 were re-examined by Dr. Douglas Symers, then Director of Pathology in New York City hospitals. He reported that adenocarcinoma was present in all the specimens previously removed and reported as peptic ulcers.

In both of these cases simple clinical deduction might lead to the belief that malignant degeneration of previously benign lesions had taken place. In one case we have gastroscopic evidence that the ulcerations had healed and atrophic gastritis was present 4 years prior to the patient's admission for a malignant condition. In the second case a careful pathological review of the microscopic sections from the two previous operations showed that the supposedly benign peptic ulcer had always been malignant.

In 1937 a series of 109 cases of gastric ulcers and 118 cases of gastric cancers were reviewed in search of evidence for the change from benign ulcer to neoplasm (18). Together with this series since 1919 we have followed 583 patients with carcinoma of the stomach who

have been admitted to our wards and 1,475 cases of peptic ulcer (of which 165 were gastric ulcers) which have been followed in our gastroenterological clinic over a 1 to 19 year period. In none of these cases was it possible to prove that malignancy had its inception in benign ulceration nor have any of the known ulcers developed malignancy.

Clinical and pathological experience in surgery warns against didactic statements concerning carcinogenesis. Isolated cases in our series might leave reasonable doubt concerning the inception of the malignant condition.

CASE 3. A 43 year old white male with a typical history of peptic ulcer over a 10 year period developed an additional severe pain radiating through the back. X ray films were interpreted as showing a large penetrating ulcer of the lesser curvature of the pars media. On resection of the stomach the lesion was suspected of malignancy on gross examination and the pathological examination showed adenocarcinoma of the stomach.

From this patient's history we can conjecture that this man had a peptic ulcer of the stomach over a long period of time suppos-

Fig. 3. The comparative results in the treatment of carcinoma of the stomach between 1919 and 1938 (Series A) with those of 1939 and 1945 (Series B)

edly verified by x ray findings, and later a malignant condition at operation. As to whether this man had both a carcinoma and a peptic ulcer at the same time, or whether he developed a gastritis which underwent neoplastic degeneration or whether the carcinoma originated at or near the peptic ulcer we do not know. Several eminent authors (4, 7, 14, 21, 27, 29) on this subject consider that the change from peptic ulcer to malignant lesion occurs frequently. Although it is possible that a neoplasm may arise at the site of the peptic ulcer in our experience this transformation is not only unusual but extremely uncommon. Whether a gastric carcinoma is early or late, small or large, it may undergo peptic ulceration eroding away all signs of malignancy (12) and at this time will give the signs and symptoms of this condition. By x ray examination it may even be mistaken for benign peptic ulcer and the malignancy may not be apparent until later. In spite of the fact that

we perform gastric resections on many patients, including those with intractable gastric ulceration as well as in any case in which there is doubt concerning the diagnosis of carcinoma, we do not believe that the potentiality of malignancy originating in a benign peptic ulcer is an indication for operation.

GASTROSCOPY

Gastroscopic examination was attempted in 28 cases. In 22 the diagnosis of carcinoma of the stomach was correctly made. One case was termed negative and 1 case diagnosed as gastric ulcer. 4 attempts to perform gastroscopic examination were considered incomplete or unsuccessful and no report rendered.

The flexible gastroscope allows visualization of the gastric mucosa and is an additional means of verifying the diagnosis of gastric cancer. The interpretation of the results of gastroscopic examination (like the results of

Fig. 4. The age and sex incidence.

any other diagnostic procedure) must be tempered with the knowledge that there is an element of error in the procedure, and also that the accuracy of the observations are dependent on the position of the lesion and the experience of the gastroscopist. However since any information concerning the condition of the gastric mucosa is of diagnostic importance gastroscopic examination should be utilized in all lesions of a questionable or controversial nature following x ray and laboratory studies.

The extensive use of this instrument by experienced observers has verified the findings of Faber and Konjetzny concerning the actuality of involutionary or retrogressive gastritis.

Chronic gastritis frequently accompanies gastric ulcers. To clarify a term, gastritis does not necessarily mean an inflammatory lesion but includes functional and pathological derangements of the glandular elements which make up the involutionary changes. As shown by Judd, definite changes in the mucosa indicative of severe chronic gastritis of long standing are present in association with gastric carcinoma. The origin of gastric cancer on a mucosa which is the seat of this pathological change has been described so frequently (5 11 12 15 22 25, 26) during the past 20 years that we believe that this change must be considered an important factor in the vast majority of cases.

Fig. 3. The comparative results in the treatment of carcinoma of the stomach between 1909 and 1945 (Series A) with those of 1939 and 1945 (Series B).

edly verified by x ray findings and later a malignant condition at operation. As to whether this man had both a carcinoma and a peptic ulcer at the same time, or whether he developed a gastritis which underwent neoplastic degeneration or whether the carcinoma originated at or near the peptic ulcer we do not know. Several eminent authors (4, 7, 14, 21, 27, 29) on this subject consider that the change from peptic ulcer to malignant lesion occurs frequently. Although it is possible that a neoplasm may arise at the site of the peptic ulcer in our experience this transformation is not only unusual, but extremely uncommon. Whether a gastric carcinoma is early or late, small or large it may undergo peptic ulceration eroding away all signs of malignancy (12) and at this time will give the signs and symptoms of this condition. By x ray examination it may even be mistaken for benign peptic ulcer and the malignancy may not be apparent until later. In spite of the fact that

we perform gastric resections on many patients, including those with intractable gastric ulceration, as well as in any case in which there is doubt concerning the diagnosis of carcinoma, we do not believe that the potentiality of malignancy originating in a benign peptic ulcer is an indication for operation.

GASTROSCOPY

Gastroscopic examination was attempted in 28 cases. In 22 the diagnosis of carcinoma of the stomach was correctly made. One case was termed negative, and 1 case diagnosed as gastric ulcer. 4 attempts to perform gastroscopic examination were considered "incomplete or unsuccessful" and no report rendered.

The flexible gastroscope allows visualization of the gastric mucosa and is an additional means of verifying the diagnosis of gastric cancer. The interpretation of the results of gastroscopic examination (like the results of

Fig. 4. The age and sex incidence.

any other diagnostic procedure) must be tempered with the knowledge that there is an element of error in the procedure and also that the accuracy of the observations are dependent on the position of the lesion and the experience of the gastroscopist. However, since any information concerning the condition of the gastric mucosa is of diagnostic importance gastroscopic examination should be utilized in all lesions of a questionable or controversial nature following x ray and laboratory studies.

The extensive use of this instrument by experienced observers has verified the findings of Faber and Konjetzny concerning the actuality of involutionary or retrogressive gastritis.

Chronic gastritis frequently accompanies gastric ulcers. To clarify a term gastritis does not necessarily mean an inflammatory lesion, but includes functional and pathological derangements of the glandular elements which make up the involutionary changes. As shown by Judd definite changes in the mucosa indicative of severe chronic gastritis of long standing are present in association with gastric carcinoma. The origin of gastric cancer on a mucosa which is the seat of this pathological change has been described so frequently (5, 11, 12, 15, 22, 25, 26) during the past 20 years that we believe that this change must be considered an important factor in the vast majority of cases.

Rigler has recently reported on the frequent occurrence (more than 8%) of carcinoma on the atrophic gastric mucosa of patients suffering from pernicious anemia. The age and sex incidence of chronic retrogressive gastritis coincides with the age and sex of the patients in both series of gastric carcinoma which we have reported (1-3). From our observations it would seem that the instigation of gastric carcinoma is much more closely related to the chronic pathological involutionary changes, which take place in the gastric mucosa than it is to benign peptic ulceration.

In reports on the endocrine nature of the gastric mucosa (1-3) we have called attention to massing of cases in the 40 to 70 year old group and the occurrence of cancer in 3-4 males for each female. Our findings in this review are practically identical with our previous studies (Fig. 4). Although we realize that carcinoma of the stomach occasionally appears in younger people, the great majority of these cases occurs after 40 and the problem of gastric carcinoma lies within this large group.

The preponderance of males and the high incidence in later life in all studies emphasize the endocrine factor in the etiology of gastric neoplasms. During that period in life when gastric carcinoma most frequently occurs there are marked changes of the content and nature of the sex hormones. Experimental work has shown (1-3) that activity of the gastric mucosa is influenced by hormones, including changes in the androgen-estrogen ratio. Although it is our belief based on the experimental results and clinical observations of ourselves and others (reviewed in previous publications 1-3) that the relationship between the hormone control of the gastric mucosa and gastric disease is an important carcinogenic factor, we fully realize that it will take further extensive experimental study to prove the various etiological agents responsible for the change from normal or pathological gastric mucosa to neoplasm.

DISCUSSION

From our findings it is evident that the outlook for the patient with gastric carcinoma continues to be dismal. Any gains that have been made are the result of improved pre-

operative and postoperative care. Parenteral administration of fluids to control biochemical changes, advances in anesthesia, and the advent of sulfonamides and penicillin have raised the rates of operability and resectability and lowered the operative mortality but have not appreciably affected the course of the disease. Comparative studies of the results from more specialized surgical clinics have shown that operability, resectability and the length of postoperative cure are greatly influenced by the selection of cases (14). But the prognosis of the patients in a large general hospital (which represents a cross-cut of the general population) remains distressingly unfavorable. The lack of time relationship between the onset of symptoms (as we now understand it) and the percentage of resectability reveals that our furthest progress has been our determined effort to diagnose late cases. The problem resolves itself to evolving a means of bringing patients with carcinoma of the stomach to operation early in their pathological course (6, 9, 12) rather than early in their clinical course. At present we operate on a curable carcinoma of the stomach by accident, or because of an extremely fortuitous early diagnosis.

Since our attempts to discover early gastric carcinoma are obviously failures, our efforts should be directed toward the improvement of our methods of diagnosis. At the present time our only method of revealing asymptomatic curable gastric cancer is by fluoroscopic and x-ray studies. The institution of these studies on a mass scale, by methods similar to those used in mass examinations for tuberculosis, offers a great opportunity to uncover asymptomatic malignant disease. The use of such a procedure has been advocated by several since 1935 (6, 18).

Comparative mass fluoroscopic and x-ray studies on approximately 400 American soldiers and 400 German prisoners with gastrointestinal complaints showed that 1 per cent of the German prisoners had carcinoma of the stomach while none was found in a similar group of American soldiers (30).¹ Although

¹It is interesting to note that the reverse age group of the German prisoners was 34 while among the American soldiers it was 8.

the study of Dailey and Miller on 500 normal people did not reveal any gastric carcinoma we believe that it must be carried out in groups larger than 1000 to be statistically valuable, and that routine annual fluoroscopic and x ray studies of the stomach especially in the carcinoma age group, should be instituted.

A recent authoritative mass fluoroscopic and x ray study (28) on a consecutive group of 2,413 patients without gastrointestinal complaints revealed that 3 had asymptomatic gastric cancer. This procedure conducted on a larger scale would undoubtedly disclose and bring to operation a higher percentage of resectable and curable patients than any other means at our disposal. The outline of a plan by which mass fluoroscopic and x ray studies of the stomach could be routinely carried out on an increasing number in the carcinoma age group is proposed.

1 Education of the public (a) on the asymptomatic character of carcinoma of the stomach (b) on the necessity for routine fluoroscopic and x ray examination of the stomach

2 Fluoroscopic and x ray studies of the stomach performed (a) as part of an annual physical examination in military services (b) as part of an annual physical examination in veterans organizations (c) as part of an annual physical examination in large industries (d) as part of an annual physical examination on members of labor unions (e) as part of a physical examination prior to the issuance of health and life insurance policies (f) as a routine procedure on all patients over 40 years of age entering hospitals

3 Availability to private physicians of facilities for fluoroscopic and x ray studies of the stomach for those on every economic level so that all patients over 40 years of age are given routine annual examinations.

4 Gastric analysis and gastroscopy as well as further repeated x ray studies in all questionable or controversial lesions found on fluoroscopic examination

In our present state of ignorance concerning carcinogenesis in general and the early diagnosis of gastric carcinoma in particular, the popularization of fluoroscopic and x ray

examinations of the stomach presents an important method of discovering an increasing number of curable cases among the general population

CONCLUSIONS

1 Comparative studies of 583 cases of carcinoma of the stomach between 1918 and 1945 demonstrate the poor prognosis and emphasize lack of progress.

2 The absence of relationship between the onset of the symptomatology operability and possibility of cure reveals our failure in the diagnosis of early cases.

3 Investigation does not substantiate the possibility of the transformation of benign ulcer to gastric carcinoma as anything but a rare occurrence

4 It is suggested that the following four factors have a definite relationship (a) age and sex incidence (b) chronic 'gastritis' (c) endocrine effects on the gastric mucosa (d) the inception of gastric neoplasm

5 A plan is presented for the utilization of mass fluoroscopic and x ray studies of the stomach, as a means of discovering curable malignant conditions

THE PHYSIOLOGIC EFFECTS OF CURARE AND ITS USE AS AN ADJUNCT TO ANESTHESIA

PHYLLIS HARROUN M D FREDERICK E. BECKERT M D and
CARL W FISHER, M D., San Francisco, California

CURARE is still a relatively unknown drug. It is known to cause complete paralysis of the skeletal muscles by inactivating acetylcholine and thus blocking nerve impulses to the voluntary muscles. This paralysis begins with the muscles innervated by the cervical nerves and continues successively through the muscles of the extremities, the abdominal muscles, the intercostals, and finally the diaphragm.

Claude Bernard in 1857 reported that curare is absorbed from subcutaneous, intramuscular and intravenous injection and by the pulmonary and rectal mucosa, but is not absorbed by the mucosa of the rest of the intestinal tract, the genitourinary tract, or through the skin. Alexander Partos in 1930 reported that curare is detoxified by the liver and can be recovered from the liver substance. He believed the curare not absorbed by the liver was excreted unchanged by the kidneys. This theory agrees with the more recent work of the pharmacologists (Squibb) who have found that 40 to 60 per cent is excreted in the urine.

ANIMAL EXPERIMENTATION

In the last 5 years the use of curare to obtain muscular relaxation in abdominal surgery has become widespread. In order to determine whether curare could safely be used to produce the apnea necessary for controlled respiration in intrathoracic operations in conjunction with nitrous oxide anesthesia the physiological effects of the drug on dogs were studied. A series of 50 dogs was given enough curare to produce apnea for from 2 to 8 hours. The first 25 dogs were given atropine 0/0006 (gr 1/100) and the second 25 morphine sulfate 0/015 (gr 1/4) or 0/03 (gr 3/4) depending on the size of the dog and atropine 0/0006

From the Subdivision of Anesthesia, Department of Surgery, University of California Medical School, San Francisco, California. Research financed in part by the Christine Breen Research Fund.

(gr 1/100). No difference was noted in the amount of curare necessary to produce apnea or the duration of the apnea in the two series.

An initial intravenous injection of 40 milligrams of curare was given (enough to cause apnea in about 2 minutes). As soon as apnea and muscular relaxation occurred an endotracheal tube was inserted and connected to a breathing bag and cylinder of oxygen. Artificial respiration was carried on by gentle intermittent pressure on the bag. We consider this a more physiological method than the use of a mechanical respirator. An oxygen flow of 7 to 8 liters per minute was maintained to prevent the accumulation of carbon dioxide in the bag. Further doses of curare were injected intravenously whenever the dogs started to breathe.

The average dose of curare in the first series of 25 dogs was 56 milligrams. Of the series 6 dogs died: 1 of deliberately produced hypoxia and respiratory acidosis; 1 of an overdose of prostigmine (2 c.c. of 1:2000); 1 of accidental failure to intubate and consequent acute anoxia; and 3 of pulmonary atelectasis after return to the cage. We found that to prevent atelectasis it was necessary to continue artificial respiration until the intercostal muscles were contracting strongly.

The second series of 25 dogs received an average dose of 88 milligrams of curare. Two of these dogs died: 1 of pneumonia during an epidemic in the animal house 4 days after the experiment and 1 of atelectasis after being returned to the cage. This last animal was deliberately sacrificed in order to impress the students with the importance of continuing artificial respiration until the intercostal muscles recover their power of contraction. In no case could death be attributed to the specific toxicity of curare.

We concluded from this series that curare of itself does not cause death in apneic doses. A

second important discovery was that artificial respiration must be continued until the intercostal muscles are contracting strongly. Discontinuing before this stage of recovery even though strong diaphragmatic contractions were present and the dogs were able to oxygenate themselves adequately resulted in death from atelectasis.

Other interesting facts came to our attention during these experiments. Although the dogs were curarized to the point of apnea if a finger was moved toward the eye without touching the lashes, hair or skin the eyelids would close. A loud noise would often cause a sudden start in a dog apparently completely paralyzed with curare. Therefore vision and hearing must still be present after curarization and their reflex arcs be intact. It was also noted that the platysma seemed much less affected by curare than the other muscles. Even though the dog was in apnea, a flea crawling on the abdominal wall would cause violent twitching of the platysma in that area. Twitching of the platysma was the first sign of recovery from curare. This was most evident in the animals which had not received morphine. These phenomena raise grave doubts in our minds that apneic doses of curare produce anesthesia or analgesia.

A rise in blood sugar was found after the injection of curare in a series of 6 dogs. The rise averaged 49.9 milligrams per cent. All these animals showed glycosuria but no acetonuria.

Electrocardiograms were taken before during and after the repeated administration of curare in a series of 4 dogs. After curare the QRS voltage decreased, the T waves became variable and according to the cardiologists the tracings resembled those seen in potassium poisoning.

Electroencephalograms were taken on a series of 5 dogs and showed identical changes in all. Control tracings were taken 1 hour after premedication with morphine and atropine. A tracing was made while the dog was in apnea following the administration of 40 milligrams of curare. When the dog had recovered from the curare sufficiently to breathe an anesthetic dose of sodium pentobarbital was injected intravenously and a third set of electroencephalograms was taken. Two days later

tracings were repeated first with morphine and atropine and then with the same dose of pentobarbital as before without curare. Compared with the control tracings, those taken following curare showed a very marked lowering of the potentials together with slight dysrhythmia. Light flashed in the eyes or loud noises caused no alteration in the picture unless the dog jumped and moved the leads. After pentobarbital more marked dysrhythmia occurred than with curare. It was concluded that large doses of curare may cause a cerebral dysrhythmia compatible with a slight narcotic effect.

It was found that the repeated administration of curare over long periods of time caused no change in the animal's reaction to the drug. Four dogs received from 6 to 10 administrations of curare each in 6 months time for periods ranging from 30 minutes to 4 hours. They showed neither increased tolerance nor sensitivity to the drug at the end of this time. After recovery they behaved in all respects like normal animals.

A cesarean section under local anesthesia was performed on a pregnant bitch while she was in apnea induced by 40 milligrams of curare and 6 pups were delivered. All the pups breathed spontaneously, moved and showed no signs of being curarized. One pup was freed from its membranes and held in the surgeon's hands, the cord pulsating, while another 20 milligrams of curare was injected intravenously into the mother still in apnea from her first dose. The pup continued to squirm and cry for 10 minutes, at which time the cord was cut. After the delivery and while the mother was still in apnea the administration of ergotrate produced normal contraction of the uterine muscle. The mother recovered with no ill effects from the curare. During a second cesarean section performed in a similar manner 4 milligrams of curare were injected into the umbilical vein of a lively breathing pup while it was still attached to the placenta, causing complete apnea in 15 seconds. The pup could not be intubated because of the minute size of the larynx and controlled respiration by squeezing the chest was carried on for about 1 hour. After 45 minutes a few diaphragmatic contractions were felt, but a little

later the heart stopped. Postmortem examination showed hemorrhages into the heart muscle. It is probable that our attempts at resuscitation were too rough.

We conclude from this experiment that in dogs curare does not pass the placental barriers or paralyze the uterine musculature.

In an attempt to determine the relation between the apneic dose and the lethal dose of curare 5 dogs were given massive quantities in a short period of time by means of slow intravenous drip. Controlled respiration with oxygen through an endotracheal tube was instituted and the dogs were maintained in this manner until they either recovered or died. The results are listed in Table I. One animal survived after the administration of 1 gram (25 times the apneic dose) of curare. One dog which received 4 grams of curare breathed spontaneously after 42 hours in apnea though it died after 55½ hours. The postmortem findings (including microscopic sections) were negative in all cases except those in which too much fluid was given or controlled respiration was improperly carried out. In contrast to Cole's conclusions in his article on the lethal dose of curare these findings lead us to believe that curare has no specific toxicity and that these deaths were due to failure to maintain normal metabolism. The only positive finding which might be attributed to curare is the anuria that occurred in the first animal which possibly was due to a fall in blood pressure.

CLINICAL USE OF CURARE

After we had satisfied ourselves that doses of curare which produce apnea are harmless provided the anesthetist cares for the patient properly, the administration of apneic doses of the drug to humans was begun. The technique as finally developed is as follows:

Induction. The patient is heavily medicated with a short acting barbiturate morphine and scopolamine, nitrous oxide and oxygen are administered with a face mask, and the anesthetist's ability to inflate the lungs is tested by pressure on the breathing bag. An apneic dose of curare usually 200 milligrams in adults is injected intravenously. Artificial respiration is instituted with the mask and bag when apnea develops. When the patient has reached a maximum state of relaxation, after approximately 5 minutes an orotracheal tube with an inflatable cuff is inserted and connected to a canister of soda lime and a breathing bag. Anesthesia is continued with the concentration of nitrous oxide and oxygen which has been previously found to keep the patient well anesthetized and well oxygenated. A Luer of curare is connected by means of a 3 way stopcock to a continuous intravenous drip inserted in a wrist vein in convenient reach of the anesthetist.

For use with children this technique has been varied somewhat, as described in detail elsewhere (6). Briefly the procedure consists of premedication with morphine and scopolamine.

mine, basal narcosis with tribromethonal (avertin) intubation with cyclopropane and maintenance of anesthesia with a high flow of nitrous oxide and oxygen in an open system. Apnea is produced and maintained with repeated doses of 30 to 40 milligrams of curare during the time the chest is open.

Maintenance Some adult patients will resume spontaneous respiration before the chest is entered. If the respirations are sufficiently deep to provide adequate inflation of the lungs, the patient is allowed to breathe spontaneously until the pleura is opened. After that curare is added in 20 to 40 milligram increments as necessary to produce and maintain respiratory arrest as long as the pleural cavity is open. In a completely curarized patient the usual signs of light anesthesia are masked by the muscular paralysis. Diaphragmatic contractions, slight muscular twitching movement of the facial muscles, or a rise in blood pressure indicate too light a plane of anesthesia and the need for an additional dose of morphine, preferably administered intramuscularly.

Terminating the anesthetic When the surgeon has effected an airtight closure of the pleura, or closure of the peritoneum in abdominal cases, pressure on the breathing bag is discontinued and the patient is allowed to build up carbon dioxide in his blood stream. If spontaneous respiration is not resumed by the time slight cyanosis occurs, controlled respiration is again instituted. This routine is repeated every few minutes until the patient breathes spontaneously. He is then allowed to breathe for himself but until the intercostal

muscles are functioning adequately an occasional squeeze of the breathing bag is given in order to prevent the upper lobes from becoming atelectatic.

When the anesthetist is satisfied that intercostal activity has returned sufficiently and it is desired to terminate the anesthetic, the breathing bag is emptied and filled with air. The lungs are then manually inflated several times with air after which the breathing bag

is disconnected from the endotracheal tube. Secretions are aspirated from the patient's tracheobronchial tree by means of a suction catheter inserted through the endotracheal tube. Secretions are similarly aspirated from the oropharynx and the endotracheal tube is removed. If the intercostal muscles have not recovered their power of contraction by the time the operation is ended the anesthetic is stopped and the patient's lungs are inflated rhythmically with oxygen or a mixture of air and oxygen. The endotracheal tube should under no circumstances be removed or the patient returned to the ward until the anesthesiologist is satisfied that the intercostal muscles are contracting vigorously. If this rule is disregarded the patient will almost invariably develop atelectasis. Prostigmine has proved to be ineffective in our hands in hastening the return of intercostal muscle contraction.

The patient is usually awake and able to answer questions before leaving the operating table, even after operations 6 hours or more in duration. However, it must be remembered that residual muscular weakness persists for several hours and makes careful aftertreatment necessary. The patient should be placed in bed on the side operated upon and turned frequently. Coughing and deep breathing should be encouraged. Oropharyngeal oxygen should be given if indicated by the presence of dyspnea, rapid pulse, or cyanosis.

This technique has been followed through out the entire series of cases whether or not the operation was intrapleural, in order to build as large a uniform series as possible for statistical purposes. It has proved extremely satisfactory in intrathoracic cases. Tables II to VII present a statistical comparison of the course during and after surgery of 175 patients anesthetized with nitrous oxide and given apnoeic doses of curare and an equal number of patients anesthetized for similar surgical procedures with ether, cyclopropane and spinal analgesia.

Advantages. The administration of curare with nitrous oxide anesthesia allows the use of the cautery inside the pleural cavity while the patient's respirations can be controlled by the anesthesiologist. It produces profound relaxation of the abdominal muscles. However, this can be obtained by other anesthetic agents if properly used. The patients receiving this type of anesthesia remain in very good condition during surgery and have fewer postoperative complications than those receiving other types of anesthesia. On the average the patients who received curare and nitrous oxide were ambulated earlier and were discharged from the hospital earlier than those in the control group.

Disadvantages. After curare is once administered the signs of anesthesia are completely masked by the muscular paralysis. During abdominal operations there have occurred sudden unpredictable bouts of strong diaphragmatic contractions which are very disturbing to the surgeons. The contractions resemble hiccup but they may well be attempts at vomiting due to too light anesthesia masked by muscular paralysis. Curare is given intravenously, which necessitates extra equipment and personnel to set it up, and its administration may be difficult in patients with poor veins. This technique requires the use of an endotracheal tube in every patient. In order to be a safe procedure it must be used only by well trained anesthesiologists.

TABLE VIII — LIVER AND KIDNEY FUNCTION

	Average preop. liver	Average post op. liver
Intravenous bipyruvic acid—50 cases	1.04	0.87
Phenol sulfonphthalein—44 cases	75.6%	73.9%

CLINICAL RESEARCH

Considerable experimental work has been carried out on these patients who received large quantities of curare.

Blood pressure It was found that the rapid injection of an apneic dose of curare (200 mgm.) to an anesthetized patient was often followed by an immediate and transient fall in blood pressure. Unless the pressure was taken within the first 5 minutes after the injection this fall was missed since the pressure rose rapidly to the precurare level.

Electrocardiograms Electrocardiograms were taken on 30 patients during nitrous oxide anesthesia just before and about 10 minutes after the injection of 200 milligrams of curare. The cardiograms after curare showed no significant changes from those with nitrous oxide and oxygen alone. In 5 cases there was a slight lowering of the T waves after curare which the cardiologists considered of no significance. It was suggested that what slight variations occurred were probably due to a change in the position of the diaphragm after it was paralyzed by curare.

Liver and kidney function The liver function was tested before and after curare in 50 cases. In most cases there was a slight decrease in liver function postoperatively. The fact that these patients had many other things done to them, such as long major surgical procedures, beside the administration of curare makes the significance of this change questionable. There was no significant change in kidney function postoperatively (Table VIII).

Blood sugar Blood sugar determinations were made on 4 patients before and after the administration of curare. The blood sugar rise in these anesthetized patients was minimal averaging 13 milligrams per cent. This fact raises the question as to whether the much greater rise in the unanesthetized dogs may be a psychic phenomenon secondary to a rise in adrenalin.

Consciousness Although we do not consider it a particularly important point, we have been interested in whether or not the injection of apneic doses of curare causes loss of consciousness. One of our patients distinctly remembered being draped for an intrathoracic

operation while she was in apnea from curare. The towel clips in her skin caused no pain. This may be because she was receiving nitrous oxide and oxygen enough for analgesia, but apparently not enough to cause loss of consciousness. If the inhalation anesthesia is stopped during an operation on a patient who is apneic from curare he will squirm and move his facial muscles. We have heard on good authority of 2 patients who received apneic doses of curare: 1 for an operation and 1 simply for experimental purposes, who were conscious and remembered it afterward. In both cases the patients suffered intense mental discomfort from their complete helplessness and inability to communicate with those around them. It is for this reason that we have hesitated to administer apneic doses to a conscious person.

With small doses up to 100 milligrams which produce muscular relaxation without respiratory paralysis, there is no loss of consciousness or analgesia whatsoever. We have tested this in 3 unanesthetized patients to whom curare was administered for relief of muscle spasm.

Some anesthetists (7-8) are using large doses of curare without any anesthetic agent for anesthesia during major surgical operations. The patients seem to have no memory of the procedure. According to the reports, much larger quantities of curare are necessary to keep these patients relaxed than we have needed in patients anesthetized with nitrous oxide.

Action on smooth muscle The action of curare on smooth muscle is still relatively unknown. We have confirmed the report of Gross and Cullen of dilatation and atony of the intestine following the administration of a large dose of curare, and the fact that the administration of morphine will prevent this dilatation of the intestine.

Placental transmission and action on uterine muscle Although we hesitate to report an isolated case, the results in this instance parallel so exactly the findings in dogs that we feel they should be included.

A hysterotomy and sterilization with curare-nitrous oxide anesthesia were performed on a 19 year old epileptic girl 4½ months preg-

nant A single dose of 200 milligrams of curare was administered 5 minutes after the nitrous oxide anesthesia was begun. The baby was delivered 40 minutes after the administration of curare, and when the patient had been in apnea for 35 minutes. The baby was too small to make any respiratory efforts but all its normal reflexes (withdrawal, knee jerks etc.) were present and as active as could be expected in a normal fetus of that size. The mother's uterine muscle contracted perfectly normally. The duration of the operation was 1 hour 40 minutes, the duration of apnea 1 hour 5 minutes. The baby of course was not viable but the mother made a normal recovery.

Action of prostigmine After the administration of large amounts of curare over long periods of time prostigmine has proved in our hands to be completely without effect. However, after a single apneic dose of curare or after smaller doses given for muscular relaxation prostigmine seems to overcome the muscular weakness of curare quite well.

Mortality We believe that in no case in this series could the death of the patient be attributed to the action of curare. Two of the patients on whom thoracic operations were performed died because of inability to cough out their secretions. The surgeons suspect that continued muscular weakness from the curare was the reason. However both patients had extensive rib resections and we believe that their difficulty lay in lack of support of the chest wall rather than muscular weakness. The fact that one died 4 days and the other 10 days following surgery would seem to confirm our opinion, in no case have we seen delayed or prolonged action of curare.

INDICATIONS FOR CURARE

Intrathoracic operations Curare is indicated in intrathoracic operations in which the surgeon desires to use the cautery. Here the combination of nitrous oxide anesthesia and apnea from curare provides excellent operating conditions with relaxed diaphragm and quiet mediastinum and no danger of explosion.

Intra-abdominal operations Curare is indicated in intra abdominal operations requiring prolonged complete muscular relaxation in pa-

tients whose condition contraindicates the use of a spinal or inhalation anesthetic in a deep enough plane to produce the degree of relaxation needed. The combination of first plane inhalation anesthesia and curare administered for relaxation certainly causes less change in pulse and blood pressure than spinal or deep inhalation anesthesia for long periods of time.

Emergency Curare is indicated in the emergency where relaxation is needed rapidly. This includes certain cases in which it becomes suddenly necessary to intubate a patient who is lightly anesthetized when a spinal unexpectedly wears off or when for some reason an operation which was expected to be extraperitoneal becomes intraperitoneal.

We believe that at present these are the only three indications for the use of curare in anesthesia. If it can be proved that curare does not affect the uterine muscle or pass the placental barriers in human beings, such operative deliveries as version and extraction and high forceps delivery will be added to the list. Curare should never be required for cesarean section since no muscular relaxation is necessary for this operation.

PREREQUISITES FOR PROPER ADMINISTRATION OF CURARE

We believe that curare is completely harmless when used by one who has sufficient understanding of its action and of human physiology to give adequate care to the patient under the influence of the drug. In the hands of technician anesthetists ignorant of its physiologic effects who use curare because of inability to produce muscular relaxation by inhalation anesthesia it is dangerous.

We believe that the anesthetist who is to administer curare, at least for intrathoracic cases should fulfill the following requirements.

First, he should have a thorough knowledge of respiratory physiology and all the changes that can take place during controlled respiration of the changes when a lung is nonfunctioning with or without its circulation intact and of how to protect normal lung tissue from contamination by secretions from diseased portions.

Second, he must be able to give good inhalation anesthesia. He must be able to relax pa-

tients with ether and cyclopropane and to give good nitrous oxide anesthesia without any hypoxia

Third, we feel that every person planning to use curare in anesthesia should learn its action without anesthesia by administering it to unanesthetized dogs. Only in this way can the differentiation between the signs of too light anesthesia and too little curare be learned

It is of the utmost importance that anesthetists using curare be thoroughly convinced that although the diaphragm has recovered its power of contraction and the patient may be able to oxygenate himself well he will die of atelectasis if controlled respiration is stopped before the intercostals have recovered. This is most forcibly impressed on an anesthetist by allowing him to curarize and maintain a few dogs alone. Sooner or later he will kill one in this manner. The postmortem findings are typical and striking. The lesson is never forgotten

The importance of postoperative care must also be stressed. Frequent turning of the patient, encouraging the patient to breathe deeply and cough and in thoracic cases the proper use of oxygen are essential

The safe use of curare depends entirely upon the knowledge of the anesthetist administering it. Its action and physiological effects should be studied by everyone who plans to use it

CONCLUSIONS

1. The use of curare in apneic doses is a safe procedure in the hands of a competent anesthetist. Its safety depends entirely upon the knowledge of the anesthetist administering the drug
2. The uterine muscle is probably unaffected by curare
3. Curare probably does not pass through the placenta.
4. No antidotes are of any value after the administration of large doses of curare except efficient artificial respiration until the intercostal muscles are contracting strongly
5. Curare has no delayed action or prolonged action when administered intravenously

6. The advantages of the use of curare with nitrous oxide anesthesia are (a) It allows the use of the cautery inside the pleural cavity while the patient's respirations can be controlled by the anesthetist. (b) It produces profound relaxation of the abdominal muscles for long periods of time with less change in pulse and blood pressure than other anesthetics. (c) The condition of the patient receiving this type of anesthesia remains good during surgery. (d) Fewer postoperative complications occur than with other types of anesthesia

7. The disadvantages of this technique are (a) In order to be a safe procedure it must be used only by well trained anesthetists. (b) Since the curare is administered intravenously extra equipment and hands are necessary. (c) It is necessary to use an endotracheal tube in every patient.

8. Further investigation is needed on the following points (a) lethal dose (b) action on uterine muscle and passage through placenta in human beings (c) production of unconsciousness or analgesia or both.

SUMMARY

A series of experiments in the administration of curare to unanesthetized dogs in doses of from 40 milligrams to 4 grams (2 to 200 cc.) is reported

A series of 175 cases in which apneic doses of curare were administered to patients undergoing major surgical procedures with nitrous oxide anesthesia is reported and compared with a similar series of cases in which other types of anesthesia were used

PREINFUSION—A STUDY IN THE PREVENTION OF HEMORRHAGIC SHOCK

H. NECHELES M.D., S O LEVINSON M D MARTHA JANOTA, M S and
FRED ARIMOTO B.S Chicago, Illinois

THE best treatment of shock is its prevention, for shock is more easily prevented than treated. This is the consensus of most workers who have studied shock in man or animal. We had noticed earlier that dehydrated animals succumbed to hemorrhagic shock sooner than well hydrated animals, and that they tolerated concentrated plasma or albumin solutions less than well hydrated animals (13). This observation led to our present work. We have attempted during the last 2 years to prevent hemorrhagic shock in dogs either by preinfusion or by increasing the quantity of fluid reinfused during experiments with graded repeated hemorrhages. No systematic study on this problem was known to us until our work was completed when Ingraham and Wiggers reported 'fluid priming' with saline solution as having a favorable effect in hemorrhagic shock in dogs. Prinzmetal and collaborators mention briefly that saline solution given to mice prior to scalding decreased mortality.

Surgeons have long recognized that dehydrated patients are poor operative risks and preoperative infusions and infusions during severe operations are being used widely. We are concerned here only in this part of preoperative care but we want to stress the importance of an adequate plasma albumin level as an important factor in the retention in the circulation of infused sodium chloride solution. At the same time particular care must be exercised in the calculation of the amount of infusion fluid, because the patient may suffer from an excess of fluid infusion. Patients may appear normal clinically before operation but yet may go into shock easily. This may be due to lack of fluid reserves or to a condition

of impending shock, where disease may have depleted reserves and diminished the resistance of the patient. Yet, blood pressure and pulse and most other determinations may yield normal values. Estimation of the blood volume and of the thiocyanate space may reveal a deficiency but these tests are difficult and normal standards and deviations are equivocal. For this reason the value of a preinfusion should be weighed for every patient on whom a major operation is planned.

METHODS

The method employed for the production of hemorrhagic shock in the unanesthetized dog has been described previously (1). In short, it consists in the hourly withdrawal of 25, 23, 21, 19, and 17 per cent of the measured blood volume and of the reinfusion of the amounts withdrawn (minus 2 per cent of each hemorrhage which is used for determinations) after an interval of 30 minutes between bleeding and reinfusion. The condition of the animals with regard to resistance to shock could be estimated by determining the arterial carbon dioxide content 30 minutes after the first hemorrhage. These critical carbon dioxide values permitted the prediction of the period of survival and the grouping of the animals according to their resistance to the experimental procedure.

In the present work the following modifications of the graded hemorrhage were employed in different groups of animals. (A) Preinfusion of an amount of fluid equivalent to 15 per cent of the control plasma volume. The duration of the preinfusion was 30 minutes. In one group of animals the first hemorrhage was performed 5 minutes after the end of the preinfusion and in another group the first hemorrhage was performed 2 hours after the preinfusion. (B) Infusion of an amount of fluid equivalent to 15 per cent of the con-

1	Saline 2 hours before	3	67	3
7	Gelatin 2 hours before		47	32

trol plasma volume in addition to the 23 per cent routinely administered at the time of the first reinfusion. The preinfusion fluid or the additional fluid infused were either saline solution 0.9 per cent, or gelatin solution. The gelatin employed was pigskin gelatin specially manufactured for biological use 8 per cent in 0.9 per cent saline adjusted to pH 7. The gelatin solution was sterile pyrogen free and nontoxic. Blood pressures were recorded continually from one carotid artery. Blood was withdrawn from one cannulated femoral artery. The following determinations were performed. During the control period and following the last (5th) hemorrhage plasma volume hematocrit hemoglobin sedimentation rate, total plasma proteins (including gelatin) albumin and globulin and arterial plasma carbon dioxide content. Arterial plasma carbon dioxide content was determined also 30 minutes after each hemorrhage, and 30 minutes after each reinfusion. The methods employed in these determinations have been described (11, 17).

The effectiveness of the preinfusion or of the larger first reinfusion were determined by comparing survival times and critical carbon dioxide values with the corresponding data of control experiments with simple graded hemorrhage as described above. Con-

trol experiments were repeated regularly during the presently reported series of experiments in order to rule out seasonal or other variations. All data were treated statistically by the chi square test, by the T test (7) or by the u test (22) and when the differences are called significant in this paper it means that they were statistically significant as indicated by these tests.

RESULTS

A Preinfusion In Table I the effect of preinfusions on the critical carbon dioxide values are compared with the "critical" carbon dioxide values in 215 control animals not receiving a preinfusion. The control subgroups 1 to 3 in Table I are unselected groups of control animals used consecutively but each group of experiments was performed at different times of the year. The size of each group was of the order of magnitude of the groups that received preinfusions. The distribution of the critical carbon dioxide values in the 3 smaller control groups did not differ statistically from the distribution obtained in the total control group of 215 animals.

We have presented evidence (1) that the arterial plasma carbon dioxide values, taken $\frac{1}{2}$ hour after a rapid hemorrhage of 25 per cent of the measured blood volume can be used to predict the resistance of the animal to further hemorrhages and to judge the effectiveness of blood or plasma substitutes. The lower this critical carbon dioxide the less resistant the dog will be to further hemorrhage or to substitution therapy. Comparing the distribution of carbon dioxide values in the control group with those of all preinfusion groups, it is evident that a shift of distribution to the right, i.e. a greater incidence of higher carbon dioxide values, has occurred. This is particularly true and significant in the case of the gelatin preinfusions 5 minutes or 2 hours before the first hemorrhage. Saline preinfusion was significantly effective only when given 5 minutes before hemorrhage, but not, when given 2 hours before the hemorrhage.

The higher plasma carbon dioxide values following preinfusions signified that the prob-

By Dr. H. Silverstone, Department of Cancer Research of Michael Reese Hospital.

ability of survival would be increased. However it was considered possible that some of the fluids given as preinfusions might produce only a temporary rise of the carbon dioxide which thus might not truly indicate actual survival as established by the control experiments. In order to answer this question we have tabulated our experiments according to the length of survival in Table II. The experiments with 5 hemorrhages and 5 reinfusions lasted 5 hours including the preliminary control period. Thus, "died during the experiment" denotes death between 1 and 4½ hours after the first hemorrhage. "Died during the night" denotes that the animal died between 3 and 15 hours after the termination of the experiment. "Survived +24 hours" denotes that the animal lived 24 hours or more after the termination of the experiment. In general the latter group of animals survived indefinitely, and most of those that died succumbed to pneumonia or to other diseases that had no direct relation to the experiment. In some animals an early infectious process like distemper may have been present before the experiment.

The control group of 41 dogs did not receive a preinfusion, and was subjected to the standard procedure of repeated hemorrhage and reinfusion of their own blood, as described above under "Methods." Preinfusion with 0.9 per cent saline 2 hours before the first hemorrhage did not benefit the animals at all but preinfusion with saline solution 5 minutes before the first hemorrhage increased survival through the experimental period somewhat. Preinfusion with gelatin solution administered 5 minutes before the first hemorrhage, significantly increased ultimate survival. Preinfusion with gelatin, given 2 hours before the first hemorrhage, did not increase ultimate survival, but increased survival through the experimental period.

Animals which, ½ hour after the first hemorrhage, have plasma carbon dioxide values of 20 volumes per cent and below have very little probability of survival under the conditions of our control experiments, than those with carbon dioxide values above 20 volumes per cent. The percentage of dogs with carbon dioxide values above 20 per cent

TABLE II—EFFECT OF PREINFUSION WITH SALINE OR WITH GELATIN ON SURVIVAL OF DOGS SUBJECTED TO GRADED HEMORRHAGE AND REINFUSION WITH THEIR OWN BLOOD

No. of Dogs	Procedure	Per cent of dogs that		
		Died		Survived +24 hours
		During experiment	During night

6 (12)	Saline 2 hours before	5	20	5
7 (100)	Gelatin 2 hours before	8	15	47

(%) Per cent of dogs with plasma carbon dioxide values above 20 volumes per cent.

(shown in brackets in Table II) was greater in those animals that received preinfusions than in the controls. Seventy-one per cent of the 41 control dogs of Table II have carbon dioxide values above 20 volumes per cent. When preinfusions had been given the following changes were observed: 85 per cent of the 26 dogs preinfused with saline solution 5 minutes and 87 per cent of the 16 dogs preinfused with saline 2 hours before the first hemorrhage had carbon dioxide values above 20 volumes per cent. The corresponding values were 100 per cent of all dogs preinfused with gelatin 5 minutes or 2 hours before the first hemorrhage.

Corresponding to the tendency to elevate the carbon dioxide value, the preinfusion tended to increase the survival time of the experimental animal.

B. Additional infusion. In the preceding experiments, preinfusion was given before the first (critical) hemorrhage and before the 'critical' posthemorrhage carbon dioxide determination had been performed. Therefore the effect of such preinfusion on the resultant 'critical' carbon dioxide values could be indirectly determined only by comparison with expectancy in normal controls as explained above. In order to evaluate the effect of infusion on the survival of dogs with a known 'critical' carbon dioxide level uninfluenced by previous infusions a different procedure

was designed. Dogs were subjected to the first hemorrhage and the critical carbon dioxide was determined. Then at the time of the first reinfusion a volume of 8 per cent gelatin solution amounting to 15 per cent of the measured control plasma volume, was given in addition to the returned 23 per cent of the dog's own blood. In order to test the value of this procedure rigidly only animals with a critical carbon dioxide below 20 volumes per cent were used. The control and the experimental group contained 16 dogs each. The mean survival time of the animals that died in less than 24 hours was 4.2 ± 1.1 hours for the control group and 7.2 ± 1.2 hours for the experimental group. Only 4 animals of the control group and 6 animals of the group with additional infusion survived the experimental period of $4\frac{1}{2}$ hours. The difference between these values approaches significant difference. In view of this it is believed that additional infusion may have some value. We did not find a significant increase in indefinite survival by this procedure. As already explained the probability of survival of animals with low arterial posthemorrhage plasma carbon dioxide values is small and possibly experimental conditions in these experiments were too severe. The mean carbon dioxide values following the second hemorrhage were significantly higher than those following the first hemorrhage in the animals which received the additional infusion while those of the control group were lower.

DISCUSSION AND CONCLUSIONS

While we feel that we have demonstrated the usefulness of preinfusion we want to stress that we do not advocate indiscriminate or excessive use of infusions before or during operations. Others have covered the field of water balance adequately and we refer to their papers (2-6, 8, 15, 16, 18, 21). Our results indicate also that in the case of persons exposed to the dangers of shock proper water reserves are essential. If a surgical patient has lost blood or excessive body fluid before operation or if a seriously sick patient is in impending shock or already in shock before operation he must be treated according to the estimated or measured losses of fluid hemo-

globin, plasma proteins, and salts, and does not fall into the category of preinfusion cases. In the preparation of surgical patients for major operations, most surgeons use 0.9 per cent saline or 5 per cent glucose or a mixture of both. If our experience in the dog can be applied to the human, gelatin solution can be recommended as superior to the crystalline solutions. This is especially true, when the solutions are given up to 2 hours before operation. It is generally agreed that crystalloid solutions rapidly leave the circulation of an animal in shock (8) and we have confirmed this earlier in our work (14). In normal man, infused saline solution cannot be found in the circulation approximately 2 hours after infusion (9). When there is an increased permeability of the capillaries or when the plasma proteins fall below a critical level, saline is especially contraindicated as an infusion fluid. Infusion of an excessive amount of saline not only tends to produce edema in a patient with a critically low albumin level, but it also further depletes the plasma proteins by washing them out into the tissue spaces as the saline rapidly leaves the circulation (2). In our experience infusing gelatin solutions to nephrotic patients with a marked edema and a critically low albumin level at times was followed by diuresis and reduction of edema. Gelatin solutions never were found to produce edema in man or in the dog.

It would seem practical therefore, to recommend the use of gelatin as preinfusion fluid before operations, and as infusion fluid during operations beginning the preinfusion only shortly before operation. In our previous work (12) and in present work under publication we have gained the impression that in man and in the dog the preparation of gelatin used was harmless even in large amounts. We have not used regularly repeated massive injections of gelatin however and it may be that difference of opinion with regard to noxious effects of gelatin infusion may be related to this factor in combination with the brand of gelatin employed (20). We have used a volume of 15 per cent of the measured plasma volume for preinfusion. This amount was found by experimentation to be optimal when infused over a 30 minute period. It

seems reasonable to assume that, in case of man, 15 per cent of the plasma volume may be taken as a starting point for the establishment of the amount of preinfusion to be used routinely. Thus in a person weighing 60 kilograms, assuming a blood volume of $1/13$ th of the body weight a total blood volume of 4.62 liters, and a plasma volume (assuming a hematocrit value of 45) of 2.54 liters are calculated. A preinfusion of 15 per cent of the plasma volume would constitute 381 cubic centimeters of a gelatin solution. This is not a large volume and we know that some surgeons use much larger volumes of saline or saline glucose solution, preoperatively. However some give the solutions subcutaneously and we have no experimental results to discuss this. We can state however, that the practice of giving solutions 12 hours in advance of an operation as used by some surgeons, does not offer any advantage in the light of our results on the dog. We have found that gelatin solutions, due to their colloidal properties, stay in the circulation for longer periods of time than do crystalline solutions and that therefore smaller volumes of gelatin than of crystalline solution may be infused in the preoperative patient.

We want to suggest that gelatin solution for preinfusion or for infusion during operation is better than saline or glucose infusion but not better than infusion of blood or plasma. However, where economic considerations or expediency of administration plays a rôle as in emergency accident cases we have used gelatin solutions extensively supplemented occasionally by packed red cells and have had gratifying results.

SUMMARY

Preinfusions of saline solution 0.9 per cent or of gelatin solution 8 per cent, given immediately before the first of a series of graded hemorrhages and reinfusions in the dog increased significantly the mean critical plasma carbon dioxide values 30 minutes after the first hemorrhage. Survival times were

prolonged significantly by the gelatin solution but not by the saline solution.

In the case of preinfusions given 2 hours before the first hemorrhage only the gelatin solutions were found beneficial in raising plasma carbon dioxide values and prolonging survival times.

When dogs with low 'critical' plasma carbon dioxide values were reinfused with their own blood plus an extra volume of gelatin solution, their survival times were prolonged.

The application of the data to the surgical patient is discussed.

Infusion of an excessive amount of saline not only tends to produce edema in a patient with a critically low albumin level, but it also further depletes the plasma proteins by washing them out into the tissue spaces as the saline rapidly leaves the circulation (2). In our experience infusing gelatin solutions to nephrotic patients with a marked edema and a critically low albumin level at times was followed by diuresis and reduction of edema. Gelatin solutions never were found to produce edema in man or in the dog.

It would seem practical therefore, to recommend the use of gelatin as preinfusion fluid before operations, and as infusion fluid during operations, beginning the preinfusion only shortly before operation. In our previous work (12) and in present work under publication we have gained the impression that in man and in the dog the preparation of gelatin used was harmless even in large amounts. We have not used regularly repeated massive injections of gelatin however and it may be that difference of opinion with regard to noxious effects of gelatin infusion may be related to this factor in combination with the brand of gelatin employed (30). We have used a volume of 15 per cent of the measured plasma volume for preinfusion. This amount was found by experimentation to be optimal when infused over a 30 minute period. It

seems reasonable to assume that, in case of man 15 per cent of the plasma volume may be taken as a starting point for the establishment of the amount of preinfusion to be used routinely. Thus in a person weighing 60 kilograms assuming a blood volume of $1/13$ th of the body weight a total blood volume of 4.62 liters, and a plasma volume (assuming a hematocrit value of 45) of 2.54 liters are calculated. A preinfusion of 15 per cent of the plasma volume would constitute 381 cubic centimeters of a gelatin solution. This is not a large volume and we know that some surgeons use much larger volumes of saline or saline-glucose solution preoperatively. However some give the solutions subcutaneously and we have no experimental results to discuss this. We can state however that the practice of giving solutions 12 hours in advance of an operation as used by some surgeons does not offer any advantage in the light of our results on the dog. We have found that gelatin solutions, due to their colloidal properties stay in the circulation for longer periods of time than do crystalline solutions and that therefore smaller volumes of gelatin than of crystalline solution may be infused in the preoperative patient.

We want to suggest that gelatin solution for preinfusion or for infusion during operation is better than saline or glucose infusion but not better than infusion of blood or plasma. However, where economic considerations or expediency of administration plays a rôle as in emergency accident cases we have used gelatin solutions extensively supplemented occasionally by packed red cells and have had gratifying results.

SUMMARY

Preinfusions of saline solution 0.9 per cent or of gelatin solution 8 per cent given immediately before the first of a series of graded hemorrhages and reinfusions in the dog increased significantly the mean critical plasma carbon dioxide values, 30 minutes after the first hemorrhage. Survival times were

prolonged significantly by the gelatin solution but not by the saline solution.

In the case of preinfusions given 2 hours before the first hemorrhage only the gelatin solutions were found beneficial in raising plasma carbon dioxide values and prolonging survival times.

When dogs with low 'critical plasma carbon dioxide values were reinfused with their own blood plus an extra volume of gelatin solution their survival times were prolonged.

The application of the data to the surgical patient is discussed.

CONGENITAL ATRESIA OF THE ESOPHAGUS WITH TRACHEOESOPHAGEAL FISTULA

THE last decade has witnessed the inclusion of several types of intrathoracic anomalies in the realm of congenital lesions amenable to surgical correction. Among these are certain malformations of the esophagus, heart, and great vessels. The most frequent type of esophageal anomaly occurs in a characteristic form in approximately 90 per cent of the cases. This form consists of an atresia of the esophagus at a level corresponding to the junction of its upper and middle thirds. In addition there is a fistulous communication between the trachea and the upper end of the lower esophageal segment. Recognized by Gibson two hundred and fifty years ago, the lesion resisted surgical correction until 1939, when Leven and Ladd independently and almost simultaneously employ

ed similar techniques and successfully circumvented the anomaly by a multiple stage operation consisting of gastrostomy, ligation and division of the tracheoesophageal fistula, and cervical esophagostomy. This procedure proved to be life-saving although it presented the additional problem of an eventual antithoracic esophagoplasty. Two years later the reconstruction of intrathoracic esophageal continuity by means of a single stage operation was successfully accomplished. This procedure has proved to be practicable and more satisfactory than has any other for a large majority of the cases for which surgical correction is undertaken.

With the realization that surgical correction offers considerable promise of cure, there has been an awakening of interest in the diagnosis of the anomaly. Even so, the period of time has been so short since surgical correction became available that the true incidence of the anomaly has not as yet been determined. It is known, however, that among the residents of the relatively small county in which the author resides, eight cases have been verified in the last eleven years, an incidence rate of one in 2,196 newborn infants.

The diagnosis of the typical form of the anomaly presents no great difficulty, as the atresia of the upper esophagus can be readily determined by the failure of a catheter to pass into the stomach. As the remote possibility of a partial esophageal obstruction with a diameter less than that of the catheter must be excluded, the completeness of the obstruction can be determined by roentgenography following the ingestion of iodized oil. In the presence of a complete esophageal obstruction the finding of air in the gastrointestinal tract

is indicative of a fistulous communication between the trachea and the lower esophageal segment

The most frequent variation of the anomaly consists of an esophageal atresia without air in the gastrointestinal tract. The failure of air to enter the stomach is due to a tracheoesophageal fistula of smaller than average size or more commonly to a rudimentary lower esophagus which does not communicate with the trachea. Tracheoscopy is helpful in such cases in order to determine whether a fistula is present or absent. A considerably less frequent variation consists of the typical anomaly with an additional fistula between the proximal esophagus and trachea. The superior fistula in this instance can be recognized by roentgen examination with ingested iodized oil or by endoscopy. Tracheoesophageal fistula unassociated with atresia is also infrequent. The diagnosis is not evident from the passage of a catheter since the esophagus is patent but is readily apparent on endoscopy or on roentgen examination with iodized oil with the patient in a prone position.

The important factors in the evaluation of operability are the size and general condition of the patient and the presence of any other anomalies. The incidence of prematurity in infants with esophageal atresia is considerably greater than in normal infants; those premature by more than three or four weeks and whose weight is less than four and a half pounds have in general a less favorable prognosis than full term infants of normal size. The outcome following surgical correction is particularly dubious in the listless premature infant who has a feeble cry and is unable to clear the respiratory tract of secretions. In the full term infant atelectasis or pneumonia can usually be corrected thereby presenting no contraindication to operation. Associated congenital anomalies with the exception of a

certain few of the cardiovascular system have been infrequent and are usually compatible with life.

The most rational procedure for the correction of the typical anomaly consists of an intrathoracic restoration of esophageal continuity. This operation is preferably performed through a right sided extrapleural approach. In spite of the small size of the infants, the exposure is entirely adequate. Division of the azygos vein is not required except in the rare instances in which the fistula enters the trachea at its bifurcation. The operation consists of transection of the lower esophagus at its junction with the trachea and closure of the opening into the trachea by suture. The lower end of the upper esophageal segment is opened to a diameter corresponding to the small diameter of the lower esophageal segment and an anastomosis is made. The practicability of this plan in a large percentage of the cases is evidenced by the fact that since 1939 an intrathoracic anastomosis has been possible in approximately 76 per cent of the forty two patients operated upon in a clinic where intrathoracic reconstruction is attempted if at all feasible. An intrathoracic anastomosis has usually been possible when air is present in the gastrointestinal tract before operation (83.3 per cent) and it has only rarely been possible in those cases without air in the stomach or intestines (20 per cent).

There is necessarily a predisposition to leakage at the site of the anastomosis if too great tension is present or if the wall of the lower esophageal segment is unusually thin. The resultant fistula to the exterior by way of the extrapleural wound invariably heals spontaneously. Although a stricture forms at the site of the anastomosis in such cases it is short and can be dilated successfully with a good functional result. A less frequent but more serious possibility following leakage of

civilian surgeons and training institutions and little opportunity for further training was offered him.

When General Omar Bradley assumed responsibility of the Veterans Administration and placed General Paul R. Hawley in charge of the hospital program they realized that a change of policy would be necessary to meet the greatly increased demands placed upon Veterans hospitals by the addition of all World War II veterans. It would have been impossible, under any circumstances, to secure the services of a sufficient number of full time physicians as Veterans Administration employees to meet existing needs alone without considering the rapidly expanding program. Therefore they sought the co-operation of the medical schools of this country and established what is spoken of as the Deans' committee program. Under this program, those medical schools, through their deans which are so geographically located and adequately staffed to undertake the program have assumed responsibility for the professional care of patients and for a resident training program in a number of Veterans Administration hospitals.

Under the supervision of Doctor Paul B. Magnuson, acting assistant medical director for Research and Education, the program has been expanded so that fifty-six class A medical schools in the country already are participating and a large number of Veterans hospitals are so administered.

Although individual variations in the Deans' committee programs exist in different medical schools, it is believed that the basic aims and functions are quite similar. The program now in operation at the Veterans Administration Hospital, Hines, Illinois, is fairly representative of most such programs and a brief discussion of its operations will be presented. This discussion will be limited to the surgical division of the hospital.

In order to render the best professional care to patients and to establish a well functioning resident training program it was necessary to establish general and specialty surgical services and attempt to place patients on services best suited to the care of their disease. After carefully analyzing figures on the admissions and duration of hospital stay of patients with varying surgical demands, it was decided that the needs of the Hospital could best be served by dividing the one thousand available surgical beds as follows: general surgery, 300; orthopedic surgery, 150; urology, 100; otolaryngology (including malignant tumors of these anatomical regions), 100; ophthalmology, 50; plastic surgery, 50; vascular surgery, 50; tumor service, 150; women's surgery, 50. Independent services in thoracic surgery and neurological surgery were established in another section of the Hospital.

It is the responsibility of the Deans' Committee representing Northwestern University, the University of Illinois and Loyola University Colleges of Medicine to recommend the appointment of a sufficient number of attending surgeons to render the best possible professional care and to train the residents adequately. It is required that all attending surgeons be veterans of World War II, be certified by their respective qualifying board or have equivalent training and be a faculty member of a participating medical school. Each surgeon must assume responsibility for the patients placed under his care and he must spend an adequate amount of time at the Veterans Hospital to carry out his responsibilities. The great majority of surgeons spend five half days per week at the Hospital. Each one has assigned to him one or more residents and a designated number of beds depending upon the number of patients that can satisfactorily be cared for by one surgeon and his resident staff. This varies with different special

surgeons, a large staff of consultants are available for lectures and demonstrations in fields in which these consultants have gained renown.

Men who desire training in the special fields of surgery are first assigned to general surgical services for a varying length of time in order to teach them the principles of surgery and of surgical technique before assigning them to their chosen field.

Of nearly one hundred and thirty residents on duty at this Hospital, sixty are being trained in surgery and the surgical specialties. With similar programs in a large number of Veterans Administration hospitals being administered by Deans' committees of various medical schools a great many World War II

veterans are having opportunities for graduate training and specialization which they would otherwise be denied.

The chief function of Veterans Administration hospitals is to administer the best possible care to men who have served their country in the armed forces and who are in need of such service. The newly created program not only is offering excellent training opportunities but is providing the veteran patient with the services of the best medical talent in the country, and is rendering him the best obtainable professional care. The greater efficiency resulting in a more rapid turnover of patients is permitting existing facilities to care for a far greater number of veterans than was true in the past.

CORRESPONDENCE

ANTERIOR TRANSPLANTATION OF POSTERIOR DELTOID FOR SHOULDER PALSY AND DISLOCATION IN POLIOMYELITIS

—A Correction.

To the Editor In connection with my article on the transplantation of the origin of the posterior deltoid for "Shoulder Palsy and Dislocation from Poliomyelitis," it should be pointed out that Dr. Frank R. Ober of Boston referred to this method which he had evidently used several times in "Lectures on Reconstruction Surgery of the Extremities of the American Academy of Orthopedic Surgeons, 1944." Although this reference was included in my article specific reference to the date of Dr. Ober's

publication was not available except to those readers who wished to develop the matter thoroughly through familiarity with the references included.

In a personal communication from Dr. Ober dated January 22, 1947, he states that he had performed the operation at least 12 years ago, which would antedate my performance of the operation on April 6, 1942. I feel that Dr. Ober should have deserved credit for prior publication of the method. My purpose in publishing this case report was to establish the permanency of the end-result and to point out the utility of the operation in the cure of recurrent paralytic dislocation of the shoulder for which purpose it was quite effective in the case recorded.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

THE SURGICAL FORUM

OWEN H. WANGENSTEEN M.D. F.A.C.S. Minneapolis, Minnesota

THE Forum on Fundamental Surgical Problems was instituted by the Board of Regents of the American College of Surgeons to provide an opportunity especially to the younger surgical group for the presentation of the results of original clinical and experimental research. The success of the undertaking appears to have been well established in its first session held in conjunction with the Clinical Congress in Boston in October 1941. The long war years interrupted further meetings until the December 1946 assembly of the Clinical Congress in Cleveland. The promise held out by the Boston meeting 5 years earlier for a keen interest on the part of practicing surgeons in the type of program provided for in the Surgical Forum was again demonstrated in the Cleveland sessions.

The Surgical Forum affords a large surgical audience the opportunity to become acquainted with the work of many productive clinical and experimental investigators through the medium of the concise presentation at the same time it accords a number of young well trained surgeons their first opportunity of a hearing before a national surgical organization. In the past, not infrequently young surgeons have found it necessary to have their work receive recognition before another audience before surgeons would deign to bear them. The late William J. Mayo felt keenly that the wisdom of age and experience should be exchanged freely with the enthusiasm of youth and that both old and young would benefit by the barter. In the main the most original contributions to surgery are made by young men. For the improvement of surgery as well as the enlightenment of surgeons with

greying hair and other marks of advancing years it is important that young productive workers in surgery be provided an opportunity early in their careers for active participation in surgical gatherings—before the ravages of time dampen their enthusiasm.

Furthermore surgeons are not long the best company for one another. Surgeons need the vitalizing influence which comes from association with workers in other fields of medicine. Hence, programs constituted year after year only from the membership of a like-minded group of men such as surgeons are likely to reveal traces of nutritive deficiencies. No group of medical men can suffer isolation long without exhibiting unmistakable evidences of want. Recognizing the great importance to surgeons of the life-giving spirit and vital sustenance to be gained through association with fellow workers in the broad domain of medicine the Board of Regents of the American College of Surgeons has authorized inclusion of papers of general interest to surgeons emanating from the pens of investigators in other provinces of medicine. The interests of the membership of a large organization are served best by provision for the most original and stimulating papers that come within the scope of concern of its auditors and that are pertinent to the occasion. It is unimportant whether the papers come from within the membership or by invitation to nonmembers. In subsequent sessions it is to be hoped that surgeons may have the opportunity of hearing similar presentations from the fruitful labors of young bacteriologists, biochemists, physiologists and pathologists especially in fields where the work touches the interests of the surgeon.

It is the professed purpose of the Surgical Forum to attempt to bring before its assembly

COLLECTIVE REVIEW

THE COURSE OF HYPERTENSION AFTER NEPHRECTOMY FOR ADVANCED UNILATERAL RENAL DISEASE

NELSON W BARKER M.D. and WILLIAM F BRAASCH, M.D., F.A.C.S.
Rochester Minnesota

IT is now more than 8 years since Butler reported successful treatment of hypertension in 2 children by nephrectomy for advanced unilateral pyelonephritis and since Walters and one of us (Barker) reported a similar result after removal of a kidney seriously damaged by chronic atrophic pyelonephritis in an adult. Since that time there have been a number of reports on the incidence of unilateral renal disease among patients who had hypertension and on the results of removal of the affected kidney. It is apparent that excellent results have followed nephrectomy in some cases and that there has been no effect on the hypertension in others.

For a patient whose primary complaints or symptoms are definitely related to an advanced surgical lesion of one kidney and who has incidental hypertension the immediate therapeutic problem is simple since nephrectomy probably would be necessary whether or not hypertension was present.

However in the treatment of a patient whose presenting problem is hypertensive disease and who does not have symptoms or physical signs suggestive of localized renal

disease the internist and urologist are confronted with two questions. First, should a urographic examination be made? Second if it is made and if local or diffuse disease of one kidney is found should the patient be subjected to nephrectomy primarily as treatment for the hypertension?

The incidence of so-called surgical renal lesions in cases of hypertension was at first considered to be high some observers stating that the lesions occurred in approximately 40 per cent of cases. It soon became apparent, however that in some cases of hypertension minor lesions of the kidney were found which were coincidental and not etiologic factors. This group included such renal lesions as ptosis, pyelectasis of slight or moderate degree, urinary infection and renal lithiasis without significant renal destruction. It has also become apparent that significant lowering of blood pressure rarely has followed nephrectomy unless the kidney was badly diseased as the result of either chronic infection such as occurs in the presence of atrophic pyelonephritis and severe hydronephrosis or extensive chronic renal tuberculosis. Even when such advanced lesions of the kidney have been found in patients who have hypertension, the effect on the blood pressure of removal of the involved kidney has been rather variable.

From the Division of Medicine and the Section on Urology
Mayo Clinic.
Read before the meeting of the American Association of
Genitourinary Surgeons, Stockbridge, Massachusetts, June 20
to 21 1946.

There are many factors involved in determining the exact incidence of surgical renal lesions associated with hypertension and the incidence is difficult if not impossible to determine. A previous review (2) of a large series of cases of hypertension in which careful urologic studies were made at the Mayo Clinic, showed that renal lesions amenable to surgical treatment occurred in less than 1 per cent of patients who had hypertension. In reviewing our cases of hypertension with renal lesions, this approximate incidence would seem to be corroborated.

In the sifting-out of renal lesions in cases of hypertension the most valuable single method of diagnosis is the excretory urogram. The urogram usually will make visible the existence of a renal lesion which may be surgical. Generally other data will be required to complete the diagnosis. No diagnostic method is available which will offer specific data as to whether or not hypertension would be eliminated if the kidney were removed. The question has been raised as to whether an excretory urogram should be made routinely in every case of hypertension. It has been our practice to make excretory urograms for hypertensive patients who (1) give a history of disease of the urinary tract (2) have microscopic hematuria or pyuria, or other manifestations suggesting disease of the urinary tract, or (3) are less than 20 years of age, if no other cause for hypertension is apparent, such as coarctation of the aorta. We have made excretory urograms for a great many other patients with hypertension who could not have been included in the above groups, but not for all and it is possible that in a few cases hypertension of renal etiology was overlooked. We have felt that excretory urograms are not of value for patients with hypertension who are more than 60 years of age or for those who have definite azotemia.

One of the most difficult problems in cases of hypertension has been to determine whether a renal lesion detected in the course of clinical examination of a patient with hypertension could be an etiologic factor or was merely coincidental. All the clinical data in such cases have been carefully weighed in the decision as to the advisability of surgical

treatment. In many cases the hypertension was known to have existed for many years, and the possibility of renal etiology seemed minimal. In other cases the renal lesion was of such a minor type that it was very evidently coincidental, and could not possibly have been an etiologic factor. In a few selected cases, although the renal lesion seemed to be a questionable etiologic factor surgical treatment was advised. Where there was a very definite renal lesion which might well be an etiologic factor operation was, of course, always advised. In the course of routine examination many instances of advanced hypertension with definite surgical lesions of the kidney were observed, but because of the patient's general condition, or because of clinical evidence of bilateral renal disease, performance of renal surgery was not advisable.

POSTOPERATIVE COURSE OF HYPERTENSION AFTER RENAL SURGERY

This report is based on a review of 61 cases. All the patients came to the Mayo Clinic primarily because of hypertension. All were found to have advanced disease of one kidney and minimal if any evidence of disease in the other kidney. All underwent removal of the diseased kidney. There were no deaths in the hospital during the postoperative convalescence. Blood pressures were checked several times from 2 to 4 weeks after nephrectomy to determine the immediate effects of nephrectomy on the hypertension. Blood pressures were checked again 2 to 4 years after nephrectomy either during a subsequent examination of the patient at the clinic or by the patient's home physician. Thirty-two patients, or slightly more than half of the total number, were examined 5 or more years after nephrectomy. The remainder either could not be traced or insufficient time had elapsed since nephrectomy in which to permit a 5 year follow up study. Results have been graded as follows: *Good*—if blood pressures, expressed in millimeters of mercury, were 150 systolic and 100 diastolic, or less. *Fair*—if blood pressures were significantly reduced, but still were above 150 systolic and 100 diastolic. *Poor*—if there was no significant effect on the blood pressure. and *Death*—if patients died during

TABLE I.—POSTOPERATIVE RESULTS 61 HYPERTENSIVE PATIENTS WHO UNDERWENT UNILATERAL NEPHRECTOMY

Result	Time after operation		
	Immediately (3 to 4 weeks)	Two years plus	Five years plus*

Total	61	61	61

*Figures in this column based on 31 traced patients.

the period of the follow up study. The results for the entire group are given in Table I. In reviewing the results of operation it is interesting to note the comparative condition of the patient at different periods after the operation. When the blood pressure was taken within 2 to 4 weeks after operation it was found that the result was either good or fair in 44 cases or 72 per cent. However when these patients were examined 2 years after operation there were only 35 patients for whom the results were good or fair or 57 per cent. Five years after operation the number of patients whose condition was described as good or fair was only 15 or 47 per cent of the 32 who were followed for that period (Table I).

Attention has been called previously to the fact that an estimate of results of renal surgery for hypertension cannot be exact unless the patients are examined as late as 2 years after operation. It was thought that if the patient's condition is satisfactory at that time, the chances are that the benefit will be permanent. However, the reduction in the percentage of good results at the end of 5 years in comparison with the percentage of good results 2 years after operation shows that this assumption was fallacious. In other words even though elimination of the kidney has a very definite effect in lowering blood pressure immediately after the operation and as long as 2 years after operation other factors may arise to cause a return of hypertension. The comparatively temporary removal of the etiologic factor in hypertension by renal surgery was not fully appreciated. That factors remain

TABLE II.—POSTOPERATIVE RESULTS 29 PATIENTS WHO HAD RENAL ATROPHY AND FIBROSIS AMONG 61 HYPERTENSIVE PATIENTS WHO UNDERWENT UNILATERAL NEPHRECTOMY

Result	Time after operation		
	Immediately (3 to 4 weeks)	Two years plus	Five years plus*

*Figures in this column based on 5 traced patients.

which may reassert themselves after the immediate benefit of renal surgery has elapsed must be admitted. Nevertheless, the fact that the blood pressure of 15 patients was approximately normal 5 years after operation demonstrates conclusively that the diseased kidney which was removed was a definite etiologic factor in the hypertension. It is also evident that elimination of the etiologic factor of hypertension as accomplished by nephrectomy was in many cases of only temporary value and that an underlying factor existed which reasserted itself to permit a return of the hypertension.

Careful review of the 26 cases in which the results of operation were classified as poor or death revealed data which were of considerable interest. It was rather noticeable that in most cases in which there was evidence of some involvement of the opposite kidney, there was little or no reduction in hypertension after nephrectomy. Cicatricial decline of the 'good' kidney is observed in many of these cases. In several cases there was less than normal function in the good kidney as shown by the results of various clinical tests of renal function. Elevation of blood urea even though moderate retardation of the secretion of phthalein, or deficiency in clearance of urea should constitute a warning against removal of one kidney as treatment for hypertension alone unless there is renal pathologic change which urgently indicates nephrectomy. In fact, several patients with clinical

TABLE III—POSTOPERATIVE RESULTS 26 PATIENTS WHO HAD HYDRONEPHROSIS AMONG 61 HYPERTENSIVE PATIENTS WHO UNDERWENT UNILATERAL NEPHRECTOMY

or urographic evidence of disease in the good kidney were observed whose general condition became worse after nephrectomy. Roentgenograms showed minute areas of calcification or small stones in both kidneys in several cases. The well kidney had been subjected to previous operation for stone in 2 cases.

The group of cases in which there was a definite reduction in blood pressure but not a return to normal is interesting. In many of these the systolic blood pressure observed before nephrectomy was more than 200 millimeters of mercury and the diastolic 120. Five years later although the blood pressure was reduced it remained between 160 and 170 systolic, and between 90 and 100 diastolic. Associated with the reduction in blood pressure there was almost invariably an improvement in the patient's general condition and well-being. In the absence of any other form of treatment, it would be logical to assume that removal of the kidney was the differential factor. It would seem very probable that the reduction in blood pressure was caused by elimination of a pressor factor which had been present in the removed kidney. In several cases of severe hypertension the blood pressure decreased almost to normal for a variable period after nephrectomy but when the patient was observed 2 to 5 years later a moderate increase in blood pressure was noted but the pressure was at a much lower level than before the operation.

In a number of cases in which the results were classified as poor the hypertension re-

mained at approximately the same level after nephrectomy but the patient's general condition was very definitely improved. Some type of renal infection had been present in most of these cases, and it is evident that removal of this infection was the cause of improvement in the patient's general condition. From the standpoint of the hypertensive disease, it is probable that both the fair results and temporarily good or fair results of only 2 years' duration can be considered of sufficient benefit to the patient to justify nephrectomy. Even a partial lowering of the blood pressure, or a temporary lowering of blood pressure for a period of 2 years, prevents part of the inevitable strain on the cardiovascular system produced by the hypertension, and thus delays the inevitable breakdown of the heart or large vessels.

The series of 61 cases can be broken down into three groups according to the nature of the disease in the kidney which was removed. In 29 cases there was marked renal atrophy and fibrosis (Table II). In each of these cases the kidney which was removed weighed less than 115 grams, and in 21 of the 29 cases the kidney weighed less than 70 grams. In most of the cases the lesion was considered to be chronic atrophic pyelonephritis. In a few it was probably congenital hypoplasia with secondary pyelonephritis. In 26 cases there was advanced hydronephrosis with evidence of previous or active infection, and with considerable destruction of the renal parenchyma by cicatrization (Table III). The function of these kidneys was markedly impaired. In the

TABLE V—RESULTS 2 YEARS AFTER NEPHRECTOMY AMONG 61 HYPERTENSIVE PATIENTS ACCORDING TO PREOPERATIVE LABILITY OF BLOOD PRESSURE

Blood pressure status	Results	
	Good or fair	Poor or death
Relatively labile	18	11
Relatively fixed	17	13

6 other cases there was advanced tuberculosis with destruction of more than 50 per cent of the renal parenchyma, sometimes with almost complete destruction of the renal parenchyma (Table IV)

The results in the three groups of cases are given in Tables II, III and IV. No definite difference in the results was noted in the three separate groups.

Of the entire 61 patients 25 were male and 36 were female. There were almost four times as many female as male patients in the group with chronic atrophic pyelonephritis and there were a few more males than females in the group with hydronephrosis. Of the entire group 64 per cent of the males and 53.7 per cent of the females still had good or fair results after 2 years.

We have been impressed by the fact that both good and poor results have followed nephrectomy on patients who had very similar renal lesions. From the standpoint of the data in this group of cases failed to yield information which would lead to a prediction as to which patients might be expected to present good and which poor results after removal of the badly diseased kidney. In this series of 61 cases the known duration of the hypertension, the known duration of the renal disease, the results of urinalysis, and the electrocardiographic observations failed to give information which would aid in the prediction of good or poor results after nephrectomy. Studies of the relative lability or fixation of the blood pressure including the cold pressor test and studies of the blood pressure after the patient had rested in bed for a period of 24 hours and failed to show differences which might aid in the prediction of results (Table V).

TABLE VI—RESULTS OF NEPHRECTOMY AS SHOWN BY RETINAL EXAMINATION 2 YEARS AFTER OPERATION 61 HYPERTENSIVE PATIENTS WHO UNDERWENT UNILATERAL NEPHRECTOMY

Keith-Wagener classification	Results	
	Good or fair	Poor or death
Group I	6	4
Group II	20	9
Group III	8	8
Group IV	4	5

*See text for explanation of this classification.

The patients were divided into four groups on the basis of retinal examination according to the Keith-Wagener classification, namely: group I—those who did not have sclerosis of the retinal arteries or retinitis; group II—those who had sclerosis of the retinal arteries but no retinitis; group III—those who had sclerosis of the retinal arteries and retinitis but without edema of the optic discs; and group IV—those who had sclerosis of the retinal arteries, retinitis and edema of the optic discs. Results which followed nephrectomy in these various groups are shown in Table VI. There were both good and poor results in all groups but relatively more good results were obtained in group II. There was no significant variation in results obtained among individuals in various age groups although results were slightly better for individuals less than 20 years of age and for those between the inclusive ages of 30 and 39 years. It is obvious that since hypertension usually occurs in the absence of severe unilateral renal disease and that severe unilateral renal disease not infrequently is found in patients who do not have hypertension, the combination of the two conditions at times may be entirely coincidental, possibly in as many as 20 to 30 per cent of cases in which both conditions are found. Even if unilateral renal disease may have been the cause of the hypertension it would seem that in a given case sooner or later irreversible vascular changes may take place diffusely in the body and in the good kidney which would prevent relief of the hypertension even if the original cause is removed. These two possibilities may explain the poor results which

followed nephrectomy in cases in which all observations seemed similar to those in other cases in which good results were obtained.

In review of the pathologic data evidence of infection either active or dormant, was noted in the tissues of all kidneys removed. In all cases of hydronephrosis, extensive pyelocystitis also was present. It has been shown both experimentally and on the basis of clinical records, that unilateral retention of urine with back pressure such as occurs with hydronephrosis in itself would not be a cause of hypertension. It would seem, therefore that the changes in the renal tissue as a result of infection probably are the important factors which favor the intrarenal secretion of pressor substances. So far no one has been able to determine the exact histologic changes which cause secretion of pressor substances. Of the various hypotheses suggested as the cause of pressor secretion intrarenal circulatory imbalance (Page and his co-workers) would seem to be most plausible. The microscopic appearance of the tissues in two atrophic pyelonephritic kidneys which have been removed for hypertension may be very similar and the hypertension may persist in one case and it may disappear in the other. There are no specific clinical, urographic, or pathologic data which would give definite preoperative indication as to the possibility of eliminating hypertension if the kidney is removed.

SUMMARY

An analysis has been made of 61 cases of hypertension in which advanced unilateral

renal disease was found and the affected kidney was removed as treatment for the hypertension.

Follow up studies in this group of cases have shown that 2 years after nephrectomy results were good in 25 cases, or 41 per cent; fair in 10 or 16.4 per cent; poor in 30, or 49 per cent, and that 6 patients, or 10 per cent were dead.

The condition of 32 patients was followed for 5 years. At the end of this time good results were present in 10 cases, or 31 per cent; fair results in 5 or 15.6 per cent; poor results in 17 or 53.4 per cent and 6 patients, or 19 per cent, were dead.

Both good and poor results were noted among patients in different age groups, in both sexes and among patients who had various degrees of severity of hypertensive disease.

Clinical analysis of these cases from the standpoint of the hypertension failed to reveal information which was of value in preoperative prediction of the effect of nephrectomy on the subsequent course of the hypertension.

No specific urologic or pathologic observations were noted in the affected kidneys which would indicate whether good or poor results would follow nephrectomy.

SURGERY OF THE HEAD AND NECK

HEAD

Cámpora, J. R. F. Corbellas, M. F. and González, J. M. L.: Eosinophilic Granuloma of the Frontal Bone (Granuloma eosinófilo del frontal) *Sem. med.*, B. Air 1946, 53 366.

A case of eosinophil granuloma of the right frontal bone is reported by the authors. The patient complained of an extremely intensive pain over the right eyebrow. On examination edema of the right frontal region and a tumefaction were found. The roentgenograms revealed an osteolytic process in the right frontal bone. The lesion 2.5 cm. in diameter had a round shape with a slightly irregular outline there were no signs of any focal reaction. From the roentgenological point of view myeloma and tuberculosis of the bone were considered.

In view of a slight fever sulfa drugs and penicillin had been given but diplopia appeared and the process showed a progression. Under local anesthesia a horizontal incision was made and a biopsy specimen was obtained.

Deep x-ray therapy caused disappearance of the symptoms. A roentgenogram taken 60 days after therapy was discontinued showed a marked reduction of the size of the lesion and an osteogenic reaction which gradually obliterated the cavity. The histological diagnosis was eosinophil granuloma. The frontal bone is the most frequent site of such lesions, as well as the failure of anti-infectious study allowed the exclusion of pyogenic, tuberculous, or tumoral etiology of the condition in this case. The histological findings suggested allergy as a possible etiologic factor. Eosinophil granuloma is a benign lesion distinct from Hand Schuller-Christian's disease. Deep x-ray therapy is the proper treatment of this condition.

Robinson, M.: Temporomandibular Joint. *J. Am. Dent. Ass.* 1946 33 1950

The action of the jaw is a reflex nonlever action. The anatomic and histological structure of the temporomandibular joint shows that it is not meant to bear heavy stresses. The jaw is not a lever of the third class. The muscles of mastication are so placed that the resultant force of their actions can be borne by the teeth the joints being left free from trauma using stress. Heavy stress is developed in the denture only during isometric muscular contraction. The normal stresses in the mandible are regulated by a positional and a masticatory reflex activity in the fifth cranial nerve, in its motor and mesencephalic nuclei. The disc is not fibrocartilage but a special

ized connective tissue which is capable of repair
NOAR D. FABRICANT M.D.

Kivimäki, J.: Recurrent Dislocation of the Mandibular Joint. *Ann. Chir. Gyn. Fenn.*, 1946, 35 99

Arthroses of the mandibular joint are characterized by pain tenderness and crackling sounds in opening and closing of the mouth. In advanced cases they often result in repeated or habitual luxation or subluxation. Although the etiology of the arthroses is unknown malocclusion and incorrect bite caused by the loss of several molars or pre-molars probably are predisposing factors. Infections of alcohol and iodine in the joint proved unsatisfactory.

The treatment of choice is surgery (ante-position of the articular disc). Recently prosthetic therapy in the form of reconstruction of the bite has been suggested. It is however more expensive and takes more time than operative treatment.

EYE

Richards, J. M., and Romaine, H. H.: Keratoconjunctivitis Sicca after Stevens-Johnson's Disease. *Am. J. Ophth.* 1946, 29 1121

In 1923 Stevens and Johnson reported a case of the purulent conjunctival form of erythema exudativum multiforme. Since then, others have reported this condition but have not mentioned keratoconjunctivitis sicca.

These authors report a case of exudative erythema multiforme which occurred in a woman following the use of belladonna and phenobarbital. The prodromal symptoms were typical of measles, but progressed to a state in which diffusely confluent erythematous maculopapular eruption enveloped the face the neck, the trunk, and the extremities in association with scattered large, confluent thin walled bullae. The patient became dehydrated prostrated and lasted about a week. The period of general involvement involved with a resultant edema, necrosis and mucopurulent discharge. There was destruction of the corneal epithelium and conjunctiva with consequent adhesions. Later there was a progressive infiltration and opacification of both corneas. As the stage of inflammation changed to catarrhal the typical signs of keratoconjunctivitis sicca appeared. There was corneal stippling and little lacrimation. Treatment was of no avail and corneal ulcers continued to recur. The vision in the left eye was markedly reduced and the right eye was enucleated because of a perforated ulcer.

ROBERT H. JOHNSON, M.D.

Castroviejo, R.: Indications for Keratoplasty
Am J Ophth., 1946, 29: 682

The surgical procedures used for the treatment of corneal opacities are keratoplasty and keratectomy the former usually being preferred because of the better results. The temporary contraindications to this surgery are inflammation, burns in which the eye has not become quiet, and glaucoma which has not been treated by the appropriate surgery.

The author divides the cases of keratoplasties and keratectomies into three main groups on the basis of their prognosis. The first group is made up of the favorable cases in which the final vision averages better than 20/50. This group includes those cases with a central corneal opacity surrounded by healthy tissue, keratoconus, and interstitial keratitis when the opacity is not too dense and extensive and when the transplant will remain in contact with fairly healthy corneal tissue.

The second group is composed of those cases less favorable for keratoplasty but likely to result in a considerable improvement of vision. In this group are most of the corneal dystrophies, the complete superficial opacities of the cornea with healthy epithelium and no superficial vascularization, superficial tear-gas burns with no vascularization and herent leukomas, descemetocoeles, and interstitial keratitis with somewhat denser opacities.

The third group is unfavorable because the transplant is likely to become opaque. Included in this group are the extensive corneal scars which go to the limbus or which have superficial vascularization, extensive leukomas in which the transplant would be surrounded in more than half its circumference by dense scar tissue, band-shaped opacities, dystrophila adiposae, deep corneal burns due to tear gas, and corneal opacities in aphakic eyes.

Fuchs's epithelial dystrophy, extensive corneal opacities with calcareous degeneration, corneal opacities caused by pemphigus, and corneal opacities with extensive anterior synechiae are not improved by keratoplasty or keratectomies. The author also advises against operating on very unco-operative patients.

EAR

Murzio, J. C.: Peripheral Facial Paralysis in Acute Otitis Media (La parálisis facial periférica en la otitis media aguda). *Sem med.*, B Air 1946, 53

34

Peripheral facial paralysis is of particular interest to the otologist because of the intimate anatomic relation of the peripheral tract of the facial nerve to the ear, the diagnostic, prognostic, and therapeutic indications of the condition, and its physical consequences, social and economic, for the patient. The facial nerve emerges from the sulcus of the bulbar protuberance, the motor and sensory roots uniting into a common trunk, and joins the auditory nerve in its entrance at the internal auditory meatus, then it continues through the fallopian aqueduct down

to the stylomastoid foramen, and after a short intraparotid course divides into two terminal branches, the temporofacial and the cervicofacial, which innervate the cutaneous facial except the superior elevator of the eyelid muscles and the neck of the corresponding side. The nervus intermedius of Wernig runs in the aqueduct and terminates at the geniculate ganglion and separates from the seventh nerve as a mixed nerve. Besides the termin. branches there are 10 collateral branches, 5 of which are intrapetrous passing through the walls of the aqueduct. The facial nerve in its course comes in contact with the auditory trigeminal, and vagus nerves, and its superficial cervical plexus. Branches are sent to the muscles of the stapes and palate, sensory fibers to the pinna, external auditory meatus, and tympanic membrane, gustatory nerves to the anterior two-thirds of the tongue, and secretory fibers to the sudoriferous glands of the face, and the salivary and lacrimal glands. Vasodilator fibers are also distributed. The stylomastoid artery and vein accompany the facial nerve in its intrapetrous course, the artery giving branches to the tip of the mastoid and tympanic cavity and it must be remembered that this neurovascular group completely fills the canal.

From the etiopathogenic and surgical viewpoint of intrapetrous facial paralysis the nerve may be divided into three segments: the first or labyrinthine segment, the second or tympanic segment and the third or mastoid segment. The facial nerve is in direct anatomic relation with the temporal bone and its anomalies of pneumatization. The tympanic portion presents little resistance to aggression because the osseous lamina separating it from the middle ear is very thin and at times dehiscence. Embryologically the aqueduct is membranous and the nerve is separated only by fibromucous membrane of the middle ear; later this groove is transformed into the osseous canal, but in the newborn it is open in part at the portion between the oval window and the horizontal semicircular canal and this dehiscence may persist throughout life. The tympanic portion presents a raised part, the eminence of the facial canal, which is inextensible and compresses the nerve during inflammations or pericititis. Small osseous cells near the geniculate ganglion may propagate infection in case of osteitis. The mastoid portion has a length of from 6 to 12 mm., a diameter of 4 mm. at the extreme superior end and a diameter of 6 mm. at the stylomastoid foramen. Processes affecting its superior third produce pressure early. In pneumatic and post-mastoidectomy mastoid processes, the osseous cells invade the walls of the aqueduct and separate its contents by thin laminae of bones, or excessive pneumatization near the internal jugular bulb may cause dehiscences. Occasionally invasion is limited to the superior third of the mastoid portion; the cells encircle it in front, on the inside, and behind, and if there is mastoiditis, the facial nerve may be harmed. The aqueduct may present compact osseous walls in its entire course and the nerve is very rarely injured.

at its exit at the stylomastoid foramen in case of apical mastoiditis. The facial nerve may transmit infection to the meninges in the same manner that the auditory nerve carries infection to the optic nerve. The middle ear and the mastoids and the aqueduct and its contents are continuous structures, therefore the virulence and type of otic infection and the mucosal reaction are blamed for the paralysis due to compression and varying degrees of toxic neuritis during acute otitis media. Intact nervous trunks are very resistant to suppuration even for months without functional disturbance but very susceptible to apparently light compressions.

In autopsies revealing osseous caries and dehiscences, the nerve bathed in pus during life never presented symptoms of facial paralysis. The cause of compression of the facial nerve in acute otitis media is not clear. It may be due to vascular congestion in inflammatory exudates or to edematous tumefaction in addition to an inextensible osseous wall. Adhesions of the nerve sheath to the periosteum of the aqueduct tend to localize the compression narrowing of the duct results from periostitis and pressure by the contents of the tympanum on the fibromucosa in case of dehiscences. Paralysis is not due to direct nerve infection but to a modification of the neurovascular apparatus produced by inflammation a toxic paralysis of the motor nerves of the vessels in the aqueduct followed by edema and degenerative lesions of the nerve. Osteitis of the facial canal is a very rare cause of paralysis, and if it occurs the nerve is deprived of its osseous covering and is exposed to inflammatory granulation tissue and infection which is likely to lead to its ultimate destruction.

Kettel performed mastoidectomy only in 37 cases for peripheral facial paralysis and found no osteitis in 7 cases. Demelius found none in 2 of 7 cases, in the 5 others the osteitis was of low grade and in 3 cases it was severe. Many mastoidectomies reveal great zones of osteitis but facial paralysis is not an absolute sign of mastoiditis. In the majority of cases it is of toxic origin. Paralysis appearing at the beginning of acute otitis media is caused by inflammation of the tympanic cavity and after the second week may be caused by mastoiditis with empyema. Tuberculosis scarlet fever pneumococcus mucosus measles and influenza otitis media are the important etiologic agents in peripheral facial paralysis. Early age is a factor and males are more susceptible than females. The incidence varies. Kopetzky found it in 3 per cent. Danelius in 1 per cent. Pollmann in 14 (0.7) of 1,823 cases. Kettel in 50 (0.5%) of 9,891 cases and the author in 5 (0.59%) of 7,844 cases.

Symptoms of peripheral facial paralysis may appear any moment in acute otitis media more commonly in the first and third weeks. It rarely is the first symptom and if it appears before tympanic perforation, tuberculosis should be suspected. The otitis may be slight and insignificant passing as a nervous complication of another cause. It appears

early in the young as the fallopian aqueduct is very thin at times dehiscant and very vulnerable to early toxemia and osteitis. There are very slight or no prodromal symptoms or the condition is preceded by auricular pains including half of the face with involuntary contraction of the facial muscles. The condition may also appear at the commencement of its complete symptomatology when there is a corresponding intrapetrous lesion of the nerve.

Treatment is essentially directed to the otitis media. For paralysis with an intact tympanic membrane early and ample paracentesis for efficient drainage and decompression is indicated, if there is a perforation mastoidectomy should be done. Conservative treatment of the otic infection is indicated if it follows a normal course and there are no definite signs of mastoid complication. Paralysis is a relative indication for mastoidectomy since it is not a sure sign of mastoiditis. Once mastoid complication is recognized immediate mastoidectomy is enough to banish the greater part of the paralysis and no operation should be done on the fallopian aqueduct. A reasonable length of time for observation should be allowed and then if faradic treatment is negative, decompression of the nerve in the aqueduct should be considered. The prognosis is generally favorable.

A. B. VICENZO, M.D.

NOSE AND SINUSES

Pomon S., Syracuse & R. Bolotow N. and Pullen, M.: Plastic Repair of the Deformed Nasal Septum. *Arch. Otolaryng.* Chic. 1946 44 141

The author challenges the contemporary orthodoxy which still adheres to the concept that maintenance of the profile projection of the nasal pyramid is dependent mainly on support furnished by the septum.

The author proves that the saddle nose created by a too generous removal of the nasal septum is not the result of removing the supports but is due to the development of internal stresses arising from cicatrization of the deskeletonized connective tissue.

The operation is described in great detail with many figures. The first steps are like those of the orthodox method of resection of the nasal septum but the author excavates the columella and places a thin cartilage graft in the bed and holds it in place with two sutures placed behind the graft. The obstructing cartilage is removed with scissors or a swivel knife as far ventrad or caudad as necessary. A quadrilateral piece of cartilage is placed beneath the perichondrial flaps and anchored by two mattress sutures.

The purpose of the cartilaginous replacement is not to furnish support since the graft having no abutment above or below can sustain no weight. Like the columellar batten it is replaced to prevent contraction of the connective tissue in the process of healing and thus the consequent distortion and saddling of the dorsum is eliminated.

JOHN F. DEXTER, M.D.

Young, F.: The Repair of Nasal Losses. *Surgery* 1946 20 670.

The object of any reconstructive surgical procedure is to restore or improve function, and, especially if the restored part is a facial feature, to approach the normal as closely as possible. This may be difficult with the nose which may have been partly destroyed by accident disease or by the treatment of any disease.

The surgeon should be thoroughly familiar with the form, structure and function of the nose. A brief review is given of the structure and function of the nose, and its relation to the face. Some emphasis is placed on the importance of a good appearance of the nose as a poor one may be a great social and economic handicap.

In the reconstructive surgery of the nose it is important to save as much normal tissue as possible as it is better than any that can be substituted. For grafting the skin of the forehead is the best as the color and texture of that skin is similar to that of the nose. The use of skin to replace destroyed nasal mucosa has its disadvantages, but skin is the best substance available.

Young gives a brief description of his plastic repair of nasal losses which is usually done in several operations. A number of diagrams are included to show the stages in his procedures. Photographs are included of several cases showing the appearance before and after the reconstruction surgery.

WILLIAM A. ARROCK M.D.

Mohs, F. E.: Chemosurgical Treatment of Cancer of the Nose; A Microscopically Controlled Method. *Arch. Surg.* 1946, 53 377.

The chemosurgical treatment of cancer of the nose has the great advantage of thorough microscopic control of the excision. This control is responsible for the unprecedented reliability and conservatism of the method.

The reliability of the method is indicated by the unusually high proportion of successful results, declares the author. Thus, for basal cell carcinoma, successful results were obtained in 98 per cent of 202 cases observed for 6 months or more, in 97.2 per cent of 109 cases observed for a 3 year period, and in 91.3 per cent of 53 cases observed for a 5 year period.

For squamous cell carcinoma the rate of cure was 93.9 per cent for the 33 cases observed for a 6 month period, 87.5 per cent for the 16 cases observed for a 3 year period, and 81.8 per cent for the 13 cases observed for a 5 year period. These results were obtained despite the fact that many of the cancers were far advanced and more than one-third had recurred after previous irradiation or surgical treatment.

The method is conservative, since only 1 or 2 mm. of tissue are removed beyond the points of actual carcinomatous invasion. The method is also useful in the treatment of various benign neoplasms and of precancerous lesions of the nose.

NOAH D. FARRICANT M.D.

MOUTH

Lee, F. C.: Orbicularis Oris Muscle in Double Hairlip. *Arch. Surg.* 1946, 53 407.

During the operations on 3 patients with double hairlip a modification of one of the usual plastic procedures was evolved. The essential feature of this change was to join the sphincter muscles of each side across the premaxilla and, to this end, it was necessary to cut deeply into the lip at right angles to its edge in order that a flap of sufficient length could be sewn to the corresponding structure of the opposite side. What was not known at the time was how much sphincter oris muscle was present. It is the purpose of this article to give the anatomy of the muscle in double hairlip.

In order to study the orbicularis oris muscle, serial sections were made of the left side of the upper lip of a 5 month human specimen having double hairlip.

It was found that this muscle is well developed at the corner of the mouth but quickly becomes thin and fragmented as the ala of the nose is reached. It is moderately effective in forming a barrier to keep the buccal glands in a posterior position in the lip.

No support was found for the view that there is a large concentration of purely sphincter muscle fibers at the corner of the mouth. JOHN F. DETZ, M.D.

Dorrance, G. M., and Brunsfield, J. W.: The Push-Back Operation for Repair of Cleft Palate. *Plast. Reconstr. Surg.* 1946, 1 145.

The "push-back" operation, first devised for congenital insufficiency of the palate, has been employed by the authors in the treatment of all varieties of cleft palate for a period of 20 years. During this time many minor changes have been made but the main idea behind the procedure has remained unchanged. The authors have seen some of the cases in which the method was employed, with or without modifications, by at least 20 different surgeons, and they believe they are now in a position to evaluate the final results which have been obtained.

Despite the fact that the authors have never known of the loss of a flap in cases in which their method was followed, they are constantly receiving inquiries as to whether or not the posterior palmar arteries should be divided. Many surgeons insist on saving the vessels. Many surgeons who use the principle of the push back do not advise the use of skin grafts to line the under surface of their flaps.

The purpose of this article is to give the indications for the push back operation, as well as the operative details and to attempt to show the necessity for following out the various steps which are recommended.

NOAH D. FARRICANT, M.D.

Adams, W. M.: The Use of the Masseter Temporalis, and Frontalis Muscles in the Correction of Facial Paralysis. *Plast. Reconstr. Surg.* 1946, 6.

Numerous techniques utilizing muscle transplants in the correction of facial paralysis have been

reported, with varying results. Many of these have been far from satisfactory. Since nerve grafting is impossible in so many of these cases at the present time the author believes that some form of muscle substitution is the only treatment which will give these patients not only support but the maximum amount of motion in the paralyzed side of the face.

In the reconstructive centers of both the Army and the Navy a large number of satisfactory and encouraging results have been obtained and these have given an increased impetus to utilize muscle substitution in facial paralysis. The transplantation of flexor muscle tendons, to do the work of the extensors has, in many cases, elicited results which appear to be startling.

Two cases are reported which give further evidence of the effectiveness obtained by the use of muscle flaps in the correction of facial paralysis. At best the procedure is a compromise. However muscle transplantation gives not only the same support accomplished by fascia strips but in addition affords voluntary motion without the distorting movements associated with nerve substitution.

NOAH D. FABRICANT, M.D.

Newman S. C., and Seabrook, D. B.: Management of Injuries to Stenson's Duct. *Ann Surg* 1946 124: 544

In the past surgery for the repair of lacerations or injuries to Stenson's duct has been unsuccessful. There have been occasional cases in which good re-

sults have been obtained in the immediate repair of injuries of this type but reports of success in the treatment of the more chronic types of fistula have been few.

The authors encountered a number of cases of injury to Stenson's duct while on duty at an Army general hospital during the years of 1943, 1944 and 1945 and as a result of their experience they have developed a general plan for the operation and care of patients with injuries of this type. No claim to originality is made since the operation has been described in principle by others. A detailed description of the procedure is given.

NECK

Grelland R.: Thyrotoxicosis at Ullevål Hospital in the Years 1934-1944 with a Special View to Frequency of the Disease. *Acta med scand.*, 1946 135: 103.

There was a gradual increase in the number of cases of thyrotoxicosis observed at the Ullevål Hospital from 1934 to 1942 with peaks in 1939 and 1941. In 1944 there was a sudden decrease in the number of cases back to the 1937 level. During the years from 1940 to 1944 there was an increase in the number of elderly patients and of men. The average duration of the disease for the 10 year period was 10½ months. An enlarged thyroid gland was found in 88 per cent, exophthalmos in 40 per cent, tremor in 72 per cent, and auricular fibrillation or flutter in 26 per cent. There were 222 women and 31 men in the study, a proportion approximate to that of a much larger study from several Scandinavian hospitals. The increases in the total cases during 1939 and 1942 and in the proportion of men were attributed to the tensions produced by the war.

In this series the systolic blood pressure was from 25 to 30 mm. above normal with no change in diastolic pressure. The mean pulse pressure was 71 mm. Hg. The heart beat was powerful and rapid with clear tones in 43 per cent, systolic murmur in 57 per cent, and of these 57 per cent 4 per cent also exhibited a diastolic precordial murmur. Twenty six per cent of 204 cases examined electrocardiographically exhibited continuous or paroxysmal fibrillation or flutter, 10 per cent exhibited myopathy, 26 per cent tachycardia, and 38 per cent a normal electrocardiogram. Auricular fibrillation in a majority of cases was associated with a previous history of acute rheumatic fever. The percentage of cases of toxic adenoma with auricular fibrillation was 31, whereas among the hyperplastic goiters there were only 17 per cent with auricular fibrillation. Thirty five per cent of all cases presented had enlarged hearts.

Although 30 per cent of the cases exhibited glycosuria, there was associated diabetes mellitus in only 2.8 per cent of the cases.

Blood cholesterol ranged from 68 to 226 mgm. per 100 c.c. (average 134 mgm.)

Fig. 1 (Newman and Seabrook) The intraoral and external probes are in position. The mass of scar tissue and the claustrated portion of the distal segment have been excised. The metal dilators, drawn to scale, are shown in the lower right hand corner. (Courtesy of J. B. Lippincott Co.)

Young, F.: The Repair of Nasal Losses. *Surgery* 1946 80 670.

The object of any reconstructive surgical procedure is to restore or improve function, and especially if the restored part is a facial feature, to approach the normal as closely as possible. This may be difficult with the nose which may have been partly destroyed by accident disease or by the treatment of any disease.

The surgeon should be thoroughly familiar with the form structure and function of the nose. A brief review is given of the structure and function of the nose, and its relation to the face. Some emphasis is placed on the importance of a good appearance of the nose as a poor one may be a great social and economic handicap.

In the reconstructive surgery of the nose it is important to save as much normal tissue as possible as it is better than any that can be substituted. For grafting, the skin of the forehead is the best as the color and texture of that skin is similar to that of the nose. The use of skin to replace destroyed nasal mucosa has its disadvantages, but skin is the best substance available.

Young gives a brief description of his plastic repair of nasal losses which is usually done in several operations. A number of diagrams are included to show the stages in his procedures. Photographs are included of several cases showing the appearance before and after the reconstruction surgery.

Mohs, F. E.: Chemosurgical Treatment of Cancer of the Nose; A Microscopically Controlled Method. *Arch. Surg.* 1946 53 337.

The chemosurgical treatment of cancer of the nose has the great advantage of thorough microscopic control of the excision. This control is responsible for the unprecedented reliability and conservatism of the method.

The reliability of the method is indicated by the unusually high proportion of successful results declares the author. Thus for basal cell carcinoma, successful results were obtained in 98 per cent of 202 cases observed for 6 months or more. In 97.2 per cent of 109 cases observed for a 3 year period and in 94.3 per cent of 53 cases observed for a 5 year period.

For squamous cell carcinoma the rate of cure was 93.9 per cent for the 33 cases observed for a 6 month period, 87.5 per cent for the 16 cases observed for a 3 year period and 81.8 per cent for the 11 cases observed for a 5 year period. These results were obtained despite the fact that many of the cancers were far advanced and more than one-third had recurred after previous irradiation or surgical treatment.

The method is conservative, since only 1 or 2 mm. of tissue are removed beyond the points of actual carcinomatous invasion. The method is also useful in the treatment of various benign neoplasms and of precancerous lesions of the nose.

Lee, F. C.: Orbicularis Oris Muscle in Double Harelip. *Arch. Surg.* 1946 53 407.

During the operations on 3 patients with double harelip a modification of one of the usual plastic procedures was evolved. The essential feature of the change was to join the sphincter muscles of each lip across the premaxilla and to this end, it was necessary to cut deeply into the lip at right angles to its edge in order that a flap of sufficient length could be sewn to the corresponding structure of the opposite side. What was not known at the time was how much sphincter oris muscle was present. It is the purpose of this article to give the anatomy of the muscle in double harelip.

In order to study the orbicularis oris muscle, serial sections were made of the left side of the upper lip of a 5 month human specimen having double harelip.

It was found that this muscle is well developed at the corner of the mouth but quickly becomes thin and fragmented as the ala of the nose is reached. It is moderately effective in forming a barrier to keep the buccal glands in a posterior position in the lip.

No support was found for the view that there is a large concentration of purely sphincter muscle fibers at the corner of the mouth. JAMES F. DEWEY, M.D.

Dorrance G. M., and Brunfield, J. W.: The Push-Back Operation for Repair of Cleft Palate. *Plast. Reconstr. Surg.* 1946 1 145.

The "push-back" operation, first devised for congenital insufficiency of the palate, has been employed by the authors in the treatment of all varieties of cleft palate for a period of 20 years. During this time many minor changes have been made, but the main idea behind the procedure has remained unchanged. The authors have seen some of the cases in which the method was employed, with or without modifications, by at least 20 different surgeons, and they believe they are now in a position to evaluate the final results which have been obtained.

Despite the fact that the authors have never known of the loss of a flap in cases in which their method was followed, they are constantly receiving inquiries as to whether or not the posterior palatine arteries should be divided. Many surgeons insist on saving the vessels. Many surgeons who use the principle of the push-back do not advise the use of skin grafts to line the under surface of their flaps.

The purpose of this article is to give the indications for the push back operation, as well as the operative details, and to attempt to show the accuracy for following out the various steps which are recommended.

NOAH D. FAHRENGUT, M.D.

Adams, W. M.: The Use of the Masseter Temporalis, and Frontalis Muscles in the Correction of Facial Paralysis. *Plast. Reconstr. Surg.* 1946 11 6.

Numerous techniques utilizing muscle transplantation in the correction of facial paralysis have been

reported, with varying results. Many of these have been far from satisfactory. Since nerve grafting is impossible in so many of these cases at the present time, the author believes that some form of muscle substitution is the only treatment which will give these patients not only support but the maximum amount of motion in the paralyzed side of the face.

In the reconstructive centers of both the Army and the Navy a large number of satisfactory and encouraging results have been obtained and these have given an increased impetus to utilize muscle substitution in facial paralysis. The transplantation of flexor muscle tendons, to do the work of the extensors, has, in many cases, elicited results which appear to be startling.

Two cases are reported which give further evidence of the effectiveness obtained by the use of muscle flaps in the correction of facial paralysis. At best, the procedure is a compromise. However muscle transplantation gives not only the same support accomplished by fascia strips but in addition affords voluntary motion without the distorting movements associated with nerve substitution.

Newman, S. C., and Seabrook, D. B.: Management of Injuries to Stensen's Duct. *Ann Surg* 1946 124: 544.

In the past surgery for the repair of lacerations or injuries of Stensen's duct has been unsuccessful. There have been occasional cases in which good re-

sults have been obtained in the immediate repair of injuries of this type but reports of success in the treatment of the more chronic types of fistula have been few.

The authors encountered a number of cases of injury to Stensen's duct while on duty at an Army general hospital during the years of 1943, 1944, and 1945, and as a result of their experience they have developed a general plan for the operation and care of patients with injuries of this type. No claim to originality is made, since the operation has been described in principle by others. A detailed description of the procedure is given.

Grelland, R.: Thyrotoxicosis at Ullevål Hospital in the Years 1934-1944 with a Special View to Frequency of the Disease. *Acta med scand* 1946 125: 108.

There was a gradual increase in the number of cases of thyrotoxicosis observed at the Ullevål Hospital from 1934 to 1942 with peaks in 1939 and 1941. In 1944 there was a sudden decrease in the number of cases back to the 1937 level. During the years from 1940 to 1944 there was an increase in the number of elderly patients and of men. The average duration of the disease for the 10 year period was 10½ months. An enlarged thyroid gland was found in 88 per cent, exophthalmos in 40 per cent, tremor in 72 per cent, and auricular fibrillation or flutter in 26 per cent. There were 222 women and 31 men in the study, a proportion approximate to that of a much larger study from several Scandinavian hospitals. The increases in the total cases during 1939 and 1942 and in the proportion of men were attributed to the tensions produced by the war.

In this series, the systolic blood pressure was from 25 to 30 mm. above normal with no change in diastolic pressure. The mean pulse pressure was 71 mm. Hg. The heart beat was powerful and rapid with clear tones in 43 per cent, systolic murmur in 57 per cent, and of these 57 per cent, 4 per cent also exhibited a diastolic precordial murmur. Twenty-six per cent of 204 cases examined electrocardiographically exhibited continuous or paroxysmal fibrillation or flutter, 10 per cent exhibited myopathy, 26 per cent tachycardia, and 38 per cent a normal electrocardiogram. Auricular fibrillation in a majority of cases was associated with a previous history of acute rheumatic fever. The percentage of cases of toxic adenoma with auricular fibrillation was 31, whereas among the hyperplastic goiters there were only 17 per cent with auricular fibrillation. Thirty-five per cent of all cases presented had enlarged hearts.

Although 30 per cent of the cases exhibited glycosuria, there was associated diabetes mellitus in only 2.8 per cent of the cases.

Blood cholesterol ranged from 68 to 226 mgm. per 100 c.c. (average 134 mgm.)

Fig. 1 (Newman and Seabrook). The intraoral and external probes are in position. The mass of scar tissue and the claustrated portion of the distal segment have been excised. The metal dilators, drawn to scale, are shown in the lower right hand corner. (Courtesy of J. B. Lippincott Co.)

Of 200 patients subjected to surgery only 1 died (0.5 per cent). The author states that the low mortality is attributable to the careful selection of patients and elaborate preoperative control and treatment.

There was little evidence that heredity, infection, administration of iodine, or the use of thyroid preparations were factors in the production of thyrotoxicosis. It was thought that the decrease in incidence of the disease during the last year of the period (1944) was due in part to undernutrition of the patients.

Psychic factors were considered important in the causation of symptoms.

CLYTON H. THURMAN, M.D.

Sikkema, S. H., Thewills, E. W., and Meyer, O. O.: Sternal Marrow Studies in Thyrotoxicosis Treated with Thiouracil and a Review of the Literature Regarding Thiouracil Effects on the Blood. *Blood. J. Hemat.* 9:46 411

The danger of the occurrence of leucopenia and agranulocytosis during thiouracil therapy has been repeatedly emphasized.

The authors present serial studies of the peripheral blood and sternal marrow in thyrotoxic patients before and after treatment with thiouracil and after thyroidectomy. They also review a total of 1,014 cases of thyrotoxicosis reported in the literature and discuss the effect of thiouracil on the blood and marrow in these cases.

Dameshek has stated that in agranulocytosis the bone marrow shows an immediate reaction with reduced numbers of granulocyte precursors and shortly thereafter a loss of mature, and then immature granulocytes takes place. If the patient survives the granulocyte precursors reappear and this is the stage which has frequently perhaps erroneously been termed maturation arrest—the mature granulocytes then reappear.

The dosage-time factor and the time factor, as well as hypersensitivity have been considered as causes of leucopenia and agranulocytosis by other authors.

The authors present a study made on 27 cases of definite thyrotoxicosis at the Wisconsin General Hospital at Madison. Studies were made of the peripheral blood and sternal marrow before treatment, after the administration of iodine, after iodine therapy and thyroidectomy, after thiouracil therapy and after thiouracil therapy and thyroidectomy.

Two patients presented complications, one, in the form of leucopenia, and the other in the form of agranulocytosis. The latter patient recovered from the agranulocytosis but developed a thyroid crisis and died.

No significant changes were found to occur regularly in the blood or marrow of patients receiving thiouracil. In certain unpredictable cases, leucopenia or agranulocytosis occurs. In both cases reported the reaction followed a period of borderline leucopenia. Not all patients with such counts progress to

a serious reaction but all patients receiving thiouracil should have leucocyte and differential counts 3 times a week and daily counts when the count drops to a borderline level (about 5,000).

Analysis of the blood and marrow findings in the 2 cases with a severe reaction shows they are consistent with the series of events described by Dameshek. The patient with agranulocytosis had a normal count before thiouracil therapy. She had 1,600 leucocytes with 16 per cent neutrophils the day preceding symptoms and on the first day of the symptoms the marrow showed a complete absence of young and adult neutrophils (as was the case in the peripheral blood). In the first few days of beginning recovery the peripheral blood showed more young than adult neutrophils. Terminally she had 16,000 leucocytes with 78 per cent total neutrophils, and final marrow examination (14 days after the previous one) revealed a reduction of the percentage of blasts to the normal range, but the increase then was chiefly in the myelocytes and metamyelocytes with only a slight return of the adult neutrophils by that date.

In the case with neutropenia the original blood and marrow observations were within normal range. The second marrow study was done 3 days before fever began—the first clinical indication. The marrow showed definite reduction in myelocytes and the metamyelocytes were few. By the time of the third sternal puncture, the patient had recovered clinically and the values were back to normal. In both cases the sequence of events is more readily correlated with the concepts of Dameshek than with the relatively prevalent idea of maturation arrest at the myelocyte stage.

The cases presented do not add much to the understanding of the mechanism of development of agranulocytosis. In the case with agranulocytosis the probable importance of the dosage-time factor has to be considered as the patient had had thiouracil for 103 days in four courses over a period of 7 months. In the case with neutropenia, sensitivity could be considered as there was an increase in eosinophils and the drug had been given for only a short time. It may be that all cases do not develop by the same mechanism.

The series is too small for definite conclusions, but in some respects tends to confirm the previous observations of others such as the following: thiouracil affects chiefly the neutrophils and particularly the younger ones, and agranulocytosis begins with alarming suddenness.

The authors believe that serial sternal marrow and blood studies fail to show any regularly occurring changes after thiouracil therapy. Changes are seen only in the few relatively unpredictable cases in which leucopenia and agranulocytosis develop. The studies support the views of Dameshek on the course of events rather than the concept of maturation arrest at the myelocyte stage.

Patients receiving thiouracil should have frequent leucocyte and differential counts.

Cattell R B: A More Optimistic Approach to Cancer of the Thyroid *West J Surg* 1946 54 444

This is the report of the experiences at the Lahey Clinic with thyroid cancer the results of which the author believes warrant a more optimistic view of the disease. Previous to January 1946 487 patients with cancer of the thyroid were treated surgically or by combined surgical and radiation therapy.

The author stresses the fact that the removal of discrete adenomas of the thyroid is of great importance in the prevention of thyroid malignancy. Twenty-six patients were found to have carcinoma in a gland removed for hyperthyroidism.

All tumors of the lateral aberrant thyroid must be considered as potentially malignant and may show definite cancer. Microscopically these tumors usually show papillary cystadenoma or papillary adenocarcinoma. The author strongly advises radical neck dissection in these cases including removal of the homologous thyroid lobe. Radiation therapy is given subsequently. Of 47 such patients 1 died of recurrent malignancy 22 months after a radical operation and radiation therapy 5 patients are now living with pulmonary metastases.

In extensive thyroid cancer as much of the gross malignancy as possible is removed tracheotomy is performed and the tube is kept in place until after the completion of the postoperative radiation therapy.

ap) Radical neck dissection is not indicated in these extensive cases. The 5 year survival rate of 231 cases of carcinoma of the thyroid is given. It varied from 80 per cent in the cases of papillary adenocarcinoma to 17 per cent in the cases with giant cell carcinoma.

I. J. LEBEMANN, JR., M.D.

LeJeune F E: Intralaryngeal Operation for Cancer of the Vocal Cord *Ann Otol Rhinol* 1946 55 531

It has been the author's experience that in certain cases of carcinoma of the larynx operation by intralaryngeal dissection can be performed with results which are equally as good as those obtained by laryngofissure if not better provided certain fundamental requirements are rigidly observed. He has operated on 39 patients with early carcinoma of the vocal cord by the intralaryngeal route and the base of the lesion was treated by electrocoagulation following the operation.

Nineteen of the patients have survived the 5 year period 15 patients are alive and well from 1 to 5 years and 3 patients have had recurrences.

The advantages of intralaryngeal extirpation are believed to be (1) simplification of the operation (2) no external incision (3) preservation of continuity of the thyroid cartilage (4) better postoperative phonation (5) shorter hospitalization and (6) good prognosis.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Groff, R. A.: The Management of War Wounds of the Cranial Cavity *Am. J. Surg.* 94b, 72-434.

Differences in climate appear to have little bearing on the methods of treating battle wounds of the head. This report originated in the China Burma India theater and coincides in principle with reports of similar cases in the other theaters of war. This is a general over-all survey of opinion in the theater; neither the specific cases nor the numbers of the cases forming the basis of the opinions are mentioned.

Certain interesting points of treatment are brought out as for instance the use of the head-down position during the early transport stages and during shock was found beneficial. Not only was shock recovered from more quickly but the position facilitated the drainage of secretions and vomitus from the trachea and bronchi. Dehydration in the tropics must be carried out if at all with caution. The cases described by the author were on the contrary given from 500 to 1,000 c.c. of normal salt solution, with or without 5 per cent glucose solution. This did not materially increase the intracranial pressure and was considered beneficial to the general welfare of the patient. Air evacuation was found satisfactory and only 1 patient required oxygen; shock did not appear to be more conspicuous.

Several technical points were brought out:

1. The necessity for water tight closure of the scalp and the necessity for roentgenograms of the skull, complete débridement with the removal of metallic objects larger than 1 cm. in diameter; a necessity. Small inaccessible metallic fragments may be left.

2. When operation is done under local anesthesia too much time need not be consumed in waiting for all signs of shock to pass off; the condition of the patients continues to improve, with suitable therapy during operation.

3. The interval between wounding and operation should not be prolonged, although the results are often better after than before 12 hours have elapsed. Wounds as old as 5 days can be closed. Dusting with sulfa powders was given up as being of no value. The dural closure controversy was here decided in favor of the American plan, i.e. closure with or without the use of transplanted tissue. There is a general résumé of the surgical technique which seems to be in accordance with the generally accepted practice of those doing the best work. ADRIEN VON BRUGNEN, M.D.

Muntoni, E.: Experimental Study of Subdural Hematoma (Studio sperimentale dell'ematoma sottodurale). *Sperimentale* 1944, 96-8.

The study of subdural hematoma has become more important as the possibility of successful surgi-

cal treatment has increased. The author made an experimental study by opening the skulls of dogs and creating subdural cavities which after from 5 to 15 days were filled with blood. Photographs of the operation and the resultant cavities are given.

A detailed comparative histological study was then made of the membrane which always forms in human subdural hemorrhage and the artificially created membrane in these cavities. Photomicrographs of the findings are given. The subdural reactions were substantially the same in the two conditions but clinically the artificially created lesions underwent a slow regression while in the clinical hematomas there was a progressive increase in size with a free interval between the occurrence of the stroke and the development of the clinical symptoms. This may have been due to the fact that the clinical hematomas were not produced entirely by the trauma; there may have been secondary factors such as changes in the blood and in the brain tissue; there may also have been localized inflammations which favor the occurrence of hemorrhage. Such constitutional factors cannot be reproduced in experimental work.

It is believed that the only histologically demonstrable difference between subdural hematomas and pachymeningitis is that in the former there is communication between the vascular lacunae and the newly-formed vessels which can never be demonstrated in the latter. The author's histological findings seem to show that the vascular lacunae are only newly formed vessels cut in different directions in different sections. ADRIEN G. MONTAG, M.D.

Hulse, V.: Primary Melanocytoblastoma of the Central Nervous System (Primäres melanocyto-blastom v. falschinf. des zentralen nerven). *Laboratory* 94b, 7-355.

A 40 year old woman without evidence of hereditary or acquired taint developed the picture of a space-occupying growth of the cerebellopontine region on the right side. The condition finally cured a spastic paralysis of both sides, but particularly of the left arm and leg with inability to walk, difficulty in speech, and a clouded and finally stuporous mentality.

At autopsy a large pigmented (black) tumor of the right pontine region involving the right pedunculus cerebri, the lateral ganglia and the floor of the fourth ventricle was found. The aqueductus syphilis was deviated to the left and there was a huge internal hydrocephalus of all the ventricles. The tumor itself was made up of elongated cells arranged in whorls, which suggested a meningioma. Cells and intercellular spaces were filled with dark pigment. There was no sharp delimitation from the nervous tissue. Nests of tumor cells were found to be discrete and at a distance from the main mass of the tumor. The

tumor mass itself displayed numerous clear areas which had become markedly dilated by the fixing process and now exhibited the structure of a honey comb type of tumor.

This type of tumor is rare and the author believes that it arises from the leptomeninges which are of neuroectodermal origin and that the tumor cells correspond in origin to the Schwann cells of the peripheral nervous system. The tumor is probably of embryonic origin tends to appear in early childhood and may be related to malformations of the central nervous system. It does not form metastases.

JOHN W. BRENNAN, M.D.

SPINAL CORD AND ITS COVERINGS

Ingebrigtsen R.: On Dislocation and Fracture-Dislocation of the Spinal Column. *Acta. chir. scand.* 1946 94 455

The author reports 5 cases of fracture dislocation of the cervical spine. Four of the patients had spinal cord symptoms in the form of paraplegias and hemiparesis the fifth patient had no neurological symptoms. The fifth and sixth cervical vertebrae were involved in 4 cases and the sixth and seventh in 1 case. Open reduction of the fracture dislocation was performed immediately after admission of 3 of the patients in the Surgical Department of the Oslo University Clinic, and was followed by respiratory death. The fourth patient was operated upon 55 days after the injury he had been treated with direct skeletal traction for 2 weeks prior to the open reduction. His functional recovery was excellent.

The author also reports on a case of fracture dislocation of the eleventh and twelfth thoracic vertebrae, with signs of a cauda equina lesion. The dislocation was reduced immediately and the patient made a satisfactory partial recovery enabling him to return to his former occupation.

Even though 3 of the 5 patients with spinal cord lesions died following early operation the author recommends open reduction for all dislocations of the spinal column without laminectomy and as soon as possible after the injury. He also states that this procedure when done early will prevent the occurrence of post-traumatic vascular disturbances of the spinal cord and avoid changes in the passage of the cerebrospinal fluid. However he does not report the presence or absence of a spinal subarachnoid block or other changes in the cerebrospinal fluid.

GEORGE PERRET, M.D.

Hyndman O. R.: Pathological Intervertebral Disc and Its Consequences. A Contribution to the Cause and Treatment of Chronic Pain Low in the Back and to the Subject of Herniating Intervertebral Disc. *Arch. Surg.* 1946 53 447

To fully understand the pathological changes in intervertebral discs in relationship to the clinical picture it is necessary to have a specific terminology. The author uses the term degenerating discs to imply that the pathological changes within the disc are con-

tinuous but at this stage have not compressed the nerve root. In a herniating disc there is a definite bulge of the annulus. However herniation is usually the result of advanced stages of degeneration. Thus it is possible to visualize 2 separate clinical syndromes—one of low back pain and the other of sciatica. That these may overlap is easily understandable.

The symptomatology in the degenerating disc is that of chronic low back pain and reflex pain down the posterior aspect of the thigh. However this sciatica extends below the knee and is not purely segmental in distribution. This usually occurs a period locally—especially the day following strenuous work. Some relief is obtained by sleeping on a firm mattress. There is no evidence of nerve root damage such as paresthesias, anesthetics or reflex changes and the pain is not aggravated by coughing or sneezing.

In the herniating disc, chronic low back pain had preceded the sciatic radicular pain in about 75 per cent of the patients. The radiating pain extends in the sciatic distribution. The pain likewise occurs periodically but when present is associated with more severe spasms of the erector spinal muscles and splinting of the spine. Coughing and sneezing usually result in exacerbation of the pain. Evidence of nerve root damage is almost invariably present.

In differentiating the reflex and radicular pain the author has used Steindler's method of injecting the points of maximum tenderness with procaine hydrochloride. The relief of pain suggests that it is reflex in origin and hence a diagnosis of myofascial syndrome is made. Another point is that in patients with degenerating disc the pain is partially relieved by getting up and about, whereas in the herniated disc the pain is aggravated by further movements or continued activity.

There are 10 significant features often present in the neurological examination. These are as follows—(1) absence of the lordotic curvature of the lumbar spine (2) physiological scoliosis, (3) spasm of the erector spinae muscles, (4) painful limitation of the back movements (5) pain on straight leg raising and the equivalent of Kernig's test (6) slight atrophy of the calf muscle in long-standing cases (7) sensory changes compatible with nerve root damage (8) tenderness to palpation and percussion over the affected region of the spine (9) tenderness along the course of the sciatic nerve (10) alteration of the patellar and Achilles reflexes. However reflex and sensory changes in the presence of a history previously described make a diagnosis of a herniating disc mandatory and it has not proved of sufficient value to differentiate between discs at the fourth or fifth interspaces. A number of rare symptoms are presented, such as pains in the neck, phantom limb foot, and rectum.

Although roentgenograms are not diagnostic there are several corroborative factors. A collapse of an interspace may be found in normal individuals and hence reliance cannot be placed on this finding.

alone. A posterior slipping is believed to be of greater importance particularly in long-standing cases. It is well to keep in mind that x-ray evidence of arthritis does not rule out a herniated disc.

The author is convincing in his reasoning that trauma is usually a secondary or aggravating factor. The annulus must be weakened by the degenerative process before trauma may produce herniation. This does not negate the possibility that trauma may be a causative factor in initiating the degenerative process; however in such cases the history should to some extent help decide the issue.

The operative procedure consists of separating the paravertebral muscles subperiosteally from the spinous processes and laminae. After rounding away the lower third of the fourth and fifth arches bilaterally, the ligamentum flavum is removed as completely as possible. In the degenerative disc the interspace is thoroughly curetted. Only in a completely sequestered nucleus may the remainder of the disc be left intact. Exploration is always done bilaterally, and at both the fourth and fifth interspaces. Spinal fusion is not performed for the herniated disc. Bed rest for at least 3 weeks is considered advisable.

Stress is placed upon the frequency of herniating discs in the intervertebral canal. These may easily be overlooked. An extensive search or exploration is not carried out when the disc is not found in the more common sites.

Results are difficult to evaluate although improvement is usually obtained in all cases when appraised at the end of 6 months. In sequestered discs the sciatica is relieved in practically 100 per cent of the cases. The degenerated disc is a more serious problem and often associated with back pain for several months after surgery. However in this group the sciatic pain is usually relieved immediately. In most industrial cases the disability is reduced from an almost total to a 5 to 10 per cent disability.

JACK T. WOOLF, M.D.

PERIPHERAL NERVES

Cannon, B. W. and Love, J. G.: Tardy Median Palsy; Median Neuritis; Median Thenar Neuritis Amenable to Surgery. *Surgery* 94:6 20 3 3.

In 9 of the 38 cases in which the syndrome of a tardy median palsy with or without neuritic pain was encountered at the Mayo Clinic operations were performed for the condition. At operation the transverse carpal ligament was divided and neurolysis was performed on the compressed median nerve. The results in these surgical cases have been satisfactory.

Zachary, R. D.: Tendon Transplantation for Radial Paralysis. *Brit. J. Surg.* 1946, 33 358.

The author reviews and summarizes the results obtained following tendon transplantation for radial paralysis in 53 patients admitted to the Wingfield Morris Hospital during the period from 1940 to 1945.

Two groups of cases are presented for comparison. In the first group (24 cases) both the flexor carpi radialis and flexor carpi ulnaris were transplanted into the extensors of the digits. In the second group (29 cases) the flexor carpi ulnaris alone was transplanted to the extensors; the flexor carpi radialis was left *in situ* for stabilization of the wrist.

Although the operations were performed by different surgeons the techniques were standard. The transplanted tendons were threaded through the paralyzed tendons and sutured with black silk. The wrist was held in extension during the operation and until a plaster cast had been applied. After a period of 3 weeks the cast was removed, and an anterior plaster splint applied. For the next 3 weeks this splint was worn at night, and for a variable period during the day. Throughout this period, the transplanted muscles were given faradic stimulation and voluntary exercise.

In 5 cases (group I) in which both flexors had been transplanted, the palmaris longus was absent, and the results were poor. Not one patient could actively flex the wrist to neutral position or extend the thumb or fingers completely. However, when the wrist was maintained passively in a neutral position, full active extension of the fingers was possible. It was evident, therefore, that a functionally good wrist would have resulted if it could have been maintained in a stable position.

In cases in which both flexors were transplanted, but the palmaris longus was present, results were better but, in many cases, still not completely satisfactory. An average of 50 per cent of function was obtained in the entire group of 24 cases.

In the second group of 29 cases, in which only the flexor carpi ulnaris was transplanted, and the flexor carpi radialis was left *in situ* for stabilization, the results were much better. Twenty-seven of the patients could extend the fingers to neutral position, 18 could extend the thumb completely, and all could flex the thumb strongly to the neutral position. The average functional result was 91 per cent.

It is concluded, therefore, that in tendon transplantation for radial paralysis, it is important to preserve an active wrist flexor to stabilize the wrist.

Barnes, R., Bacsich, P., Wylburn, G. M., and Kerr, A. B.: A Study of the Fate of Nerve Homografts in Man. *Brit. J. Surg.* 1946 34 34.

The present article was written with the idea of discouraging the use of nerve homografts for the repair of large nerves of the extremities in man, and to show the condition of homografts which have proved to be unsuccessful.

The authors have placed 8 large homografts measuring from 7 cm. to 25 cm. in length. In no case were they satisfied with the results. Seven of the 8 grafts were removed after varying lengths of time from 140 to 904 days after grafting.

The nerve grafts were re-innervated for lengths varying from 10 to 25 mm. The authors do not be-

have there is any relationship to vascularity, but accept the suggestion of Seddon and Holmes that neurotization occurs only during the latent period before the host acquires an active immunity to the homograft. They believe that success might be greater if the nerve fibers reached the peripheral stump while the graft was still in a condition to act as a scaffold. They observed a fascicular necrosis which was later followed by a fascicular fibrosis. It was difficult to distinguish the older grafts from the surrounding tissue, which suggested that ultimately there is a total replacement of graft by the tissues of the host.

DANIEL ROOE, M.D.

Wertheimer, P.: Repair of Traumatic Loss of Substance of the Nerve Trunks of the Limbs. A Physiopathological Study (*Réparation des pertes de substance traumatiques des troncs nerveux des membres. Étude physiopathologique*). *J. chir.*, Paris 1946 62: 258.

This is a very brief report on the abundant literature of the last few years on the repair of traumatic nerve losses. The important work of American and English authors during the war has especially increased our knowledge of the problems involved.

The author mentions the recent research concerning the structure of nerve protoplasm, the endoneurial circulation of tissue fluid, the phenomena of diffusion and osmosis observed in the nerve trunks, and the work on the arterial supply of nerves which is of special importance for the repair of injured nerves. The fact that nerves show great resistance to ischemia is explained by the presence of a longitudinal intraneural network of anastomoses.

Much work has been done on degeneration and regeneration of the nerves. After severance two processes start: destruction and disappearance of the myelin at the distal stump and proliferation of the Schwann cells. This proliferation reaches its maximum on the twentieth day, then decreases gradually. Regeneration can occur only if the axils cy-linders of the proximal end are permitted to come in contact with and penetrate into the Schwann tubes of the distal end. This is dependent on the physical, chemical, and circulatory factors.

SYMPATHETIC NERVES

Weddall, G. Macbeth, R. G. Sharp, H. S., and Calvert, C. A.: The Surgical Treatment of Severe Epistaxis in Relation to the Ethmoidal Arteries. *Brit. J. Surg.* 1946 33: 387.

Occasionally epistaxis is so severe that it fails to respond to local measures such as packing and coagulation, and surgical intervention is resorted to.

The blood supply of the nasal cavities is derived from two chief sources: the sphenopalatine and facial arteries which arise from the external carotids, and the anterior and posterior ethmoidal arteries which are branches of the ophthalmic artery which, in turn, springs from the internal carotid.

The sphenopalatine and facial arteries enter the nasal cavities through their lateral walls while the ethmoidals enter through the roof. The former are more accessible to local treatment through the nares than are the latter. However many cases of epistaxis are due to injury or disease in which there is distortion of the nasal cavities, which makes them even less amenable to local therapy.

In the past, uncontrolled epistaxis has usually been treated first by ligation of the external carotid artery in the neck, and then by ligation of the internal carotid if the former failed. Ligation of the external carotid is designed to stop bleeding from the sphenopalatine artery while ligation of the internal carotid is designed to check hemorrhage from the ethmoidals.

The authors believe that while the former procedure is often justified the latter is justified only when there is rupture of an intracranial aneurysm into an accessory air sinus. In other cases in which it is desired to simply control bleeding from the ethmoidals ligation of the internal carotid usually does little good because of the large collateral circulation from the opposite side through the circle of Willis. Also the procedure is rather dangerous because of the possibility of producing cerebral ischemia.

The procedure recommended by the authors is as follows: the approximate site of the hemorrhage is determined. If it is from the lateral wall of the nasal cavity, the external carotid artery in the neck is ligated. If however it arises from the roof of the nasal cavity the authors suggest ligation or coagulation of the ethmoidal arteries in the orbit.

The operative technique is described. It is considered a fairly simple and safe procedure.

Seven cases of epistaxis are reported in which the hemorrhage was not controlled until the ethmoidal arteries on the affected side had been occluded. In two of these, the common carotid had been ligated in the neck without relief of the hemorrhage.

ROBERT E. GREEN, M.D.

Fontaine, R., Forster, E., and Stefanini, C.: Late Results of 63 Splanchicectomies Done for Various Diseases Except Chronic Arterial Hypertension (*Résultats éloignés de 63 splanchicectomies pour diverses affections en dehors de l'hypertension artérielle chronique permanente*). *Lyon chir.* 1946 41: 279.

The authors, trained by R. Leriche, report the results of 63 splanchicectomies done on 47 patients during the years from 1940 to 1945. By splanchicectomy they usually mean a section of the greater splanchnic nerve with resection of the external horn of the celiac ganglion and of the first 2 or 3 lumbar sympathetic ganglia. The lesser and least splanchnic nerves were also cut whenever they could be identified.

This procedure was done bilaterally on 9 patients and unilaterally on 5 patients suffering from thromboangitis obliterans (*arteritis obliterans*). Remission of all symptoms was observed in 5 cases. 7 other cases were much improved by the procedure while

in 2 the improvement was only temporary. The cause of this disease is still unknown and the authors are aware that their treatment is not etiological. Although they believe that thromboangitis obliterans may be due to endocrine disturbances especially of the adrenal glands they find that they get better results with splanchnicectomies than with the removal of the adrenal glands. The section of the splanchnic nerves deservates the adrenals while the lumbar sympathectomy improves locally the colateral circulation in the involved extremity.

Their results are not as good in Raynaud's disease. They report on 3 cases, 2 of which showed improvement following bilateral splanchnicectomy upper lumbar sympathectomy removal of the left adrenal gland and extirpation of both stellate ganglia. Realizing that Raynaud's disease cannot be cured with certainty by an intervention on the sympathetic chain or its postganglionic fibers, the authors come to the conclusion that this disease must be associated with the autonomic function of the arterioles and the capillaries. They believe that the surgical procedures are done too far away from the seat of the abnormal vasoconstrictive phenomena.

They have found that by doing a bilateral splanchnic block they were able to benefit greatly those patients suffering from dysphagia due to megacystophagus. Therefore, they performed a unilateral splanchnicectomy in 1 of 2 patients suffering from megacystophagus, and a bilateral thoracic splanchnicectomy with removal of the tenth and eleventh dorsal sympathetic ganglia in the other. Their results were not good and the patients had to have a cardiectomy. Because of the beneficial effect of amylnitrite inhalations and of repeated local infiltrations of the splanchnic region, the authors conclude that to be

effective in cases of megacystophagus, the operation should be done on the most peripheral nerve first, and they advocate a periesophageal sympathectomy.

Their results were much better in 11 women patients with megacolon. In these cases they did a unilateral or bilateral resection of the splanchnic nerves and of the first and second lumbar sympathetic ganglia. They report excellent results in 6 cases, great improvement in 2 cases and poor results in 3 cases.

The authors also report 12 cases of partial hydronephroses treated by unilateral splanchnicectomy with resection of the upper 2 lumbar sympathetic ganglia, or by splanchnicectomy associated with removal of the aorticorenal ganglion. Both types of procedure gave identical results: their effect on pain is usually immediate and lasting, but their action on the dilatation of the pelvis of the kidneys and the ureters is less certain and not constant. The results were good in 9 cases, fair in 2 and poor in 1 case.

The authors also report on 2 cases of intestinal vomiting without organic cause in which a left splanchnicectomy and upper lumbar sympathectomy were done with good results in 1 case. A bilateral splanchnicectomy was also done as a last resort in 1 case of chronic pancreatitis and resulted in the disappearance of the pain. Two patients with visceral tuberculosis were also treated by thoracic splanchnicectomies and resection of the tenth and eleventh dorsal sympathetic ganglia: the pain was relieved in 1 of them.

The authors have not included in this series the results of similar operations done on 25 other patients for similar afflictions within the last year. Their operative mortality was 1 per cent.

GEORGE PRAXEL, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Webster J. P.: Mastectomy for Gynecomastia through a Semicircular Intra-Areolar Incision. *Ann Surg* 1946 124 557

Gynecomastia or abnormal enlargement of the male breast is a condition in which the appearance of the breast simulates that of the female. The condition may be unilateral or bilateral. The author presents an operation for its correction which has been employed on 32 breasts in a series of 17 cases. There are three classes of benign hypertrophy of a permanent nature which necessitate treatment: (1) penducular connective tissue hypertrophy with out adipose tissue change; (2) increase in the amount of both of these elements; and (3) adipose tissue hypertrophy alone.

The author discusses the three classes of cases and then discusses the methods of treatment advocated which are radiotherapy, endocrine therapy and operation. Surgical removal of the excess breast tissue seems to be the best method for the correction of the condition. The indications for operation are to remove the threat of subsequent malignant changes in the enlarged breast to relieve pain and to prevent the psychic trauma caused by the feminine appearance of the breasts. The author discusses the operative technique very completely and summarizes as follows:

Mastectomy through a semicircular intra-areolar incision for the correction of gynecomastia is a procedure which offers many advantages over operation through other types of incision. The results of this procedure on 32 breasts were almost uniformly excellent: the insufficient reduction in the size of the breasts in 8 cases and the deformities of the nipples from necrosis in 1 case being the only exceptions. The final appearance in all cases may be favorably compared with the results obtained by other procedures. The absence of noticeable scars such as occur with extra-areolar incisions together with the reduction of the breasts to normal size and contour removes the cause of the patient's psychic disturbance. Since the normal appearance of the male pectoral region is achieved by this operation with almost no evidence of operative interference, the patient can indulge in normal activities and expose his chest without fear of ridicule or need of explanation.

The operation requires careful technique and meticulous hemostasis together with considerable skill, judgment and patience on the part of the operator to remove a proper amount of tissue along optimum planes and to close the wound satisfactorily in the depths as well as on the surface. It is believed, however, that this type of operation, which leaves inconspicuous scars should be employed when mastectomy for gynecomastia is to be performed.

PAUL MERRILL, M.D.

TRACHEA, LUNGS, AND PLEURA

Kay E. D.: Pulmonary Actinomycosis. *Ann Surg* 1946 124 535

Patients with pulmonary actinomycosis present a challenge with regard to therapeutic measures. In a series of 1,330 cases of active actinomycosis collected by Cope the thorax was involved in 15 per cent. The author discusses earlier treatments and shows that they were unsatisfactory. He presents 2 case reports which serve to illustrate the chronicity of pulmonary actinomycosis and its resistance to therapy. Both cases were subjected to pneumonectomy plus chemotherapy and the author gives the following summation:

Two case histories of patients with pulmonary actinomycosis are presented. Both patients were treated with an intensive course of sulfadiazine and penicillin therapy used both alone and in combination almost continuously over a period of a year. This therapy appeared to be of value only during the periods of exacerbation and had no permanent effect upon the progress of the disease as a whole. After a year's therapy in both patients without significant benefit apparent successful results were attained following pneumonectomy. During the postoperative period intensive therapy with sulfadiazine and penicillin given both systemically and intrapleurally was used. It is believed that patients with pulmonary actinomycosis who fail to improve following intensive adequate courses of chemotherapy should be treated by pulmonary resection while the disease is still limited to the lung and before the development of multiple thoracic sinuses.

PAUL MERRILL, M.D.

Santy Bernard, Galy, Magnin and Papillon: Stenosis of the Large Bronchi in the Course of Chronic Tertiary Pulmonary Tuberculosis in the Adult (Sténoses des grosses bronches au cours de la tuberculose pulmonaire chronique tertiaire de l'adulte). *Arch. méd. chir. exp. resp. Par.*, 1942-1945 15 189.

The authors discuss stenosis of the large bronchi in the course of pulmonary tuberculosis and describe 10 cases illustrated with roentgenograms and drawings. This stenosis may occur in a bronchus which drains a tuberculous area, or in a tributary bronchus which drains a normal area. There are certain clinical signs such as attacks of coughing resembling whooping cough, asthmatic attacks and wheezing but diagnosis is made largely by roentgen examination and bronchoscopy. Atelectasis frequently occurs in conjunction with this condition. Residual stenosis and bronchiectasis may persist at the base after the healing of the primary apical lesion.

The question of treatment in these cases of bronchial stenosis is a difficult one. The authors do not

think it necessary to give up artificial pneumothorax because of the occurrence of a bronchial stenosis. The decision depends rather on the course of the parenchymatous lesions and on whether any substitute treatment is available. There has been a great deal of discussion as to whether thoracoplasty should be performed on a cavity in the field of a stenotic bronchus. The question is not yet definitely settled. In the one case in which the authors attempted such a thoracoplasty it was a failure, but they do not believe the stenosis of the bronchus was entirely responsible for the failure. For the treatment of the stenosis itself, powdering with cocaine or adrenalin followed by aspiration of the pus and intra-tracheal instillation of antiseptic oil have been recommended. This treatment brought about improvement in 2 of the authors' cases. 1 patient developed intolerance for novocain and in 1 case the patient died in spite of the treatment. Dilatation with bougie improves drainage but in the majority of cases does not bring about definite obliteration of the cavity. Surgical removal of the affected and bronchiectatic lobes seems to be the logical treatment in spite of its severity. Although the mortality is high the patient is certain to die if not treated.

The question of whether the bronchial lesions are specifically tuberculous has been much discussed. In the 3 of the authors' cases in which careful histological examinations were made no specific tuberculous lesions were observed.

ACTLEY G. MORGAN, M.D.

Brantigan O. C.: Open Pneumonolysis. *J. Thorac. Surg.* 1946 3: 341

The advances in medicine and surgery that favorably influence the results in open pneumonolysis are many. These advances, when applied clinically have eliminated most of the morbidity and mortality associated with past attempts at open pneumonolysis. Pneumothorax should not be carried out when the patient has a large tension cavity. Also when either fibrotic or tuberculous bronchial stenosis exists, pneumothorax should not be instituted nor should it be continued when atelectasis occurs. The necessity of doing open pneumonolysis is thus eliminated in this group of patients in whom complications are frequent and serious under pneumothorax therapy alone. Fewer patients need open pneumonolysis because the closed release of adhesions is highly effective. Thus, when a patient is selected for an open operation no surprise or unexpected contraindications will be found when the pleural cavity is opened.

Rigid indications and contraindications for open pneumonolysis were adopted in an endeavor to keep the operation free of morbidity and mortality. The following indications have been used.

The patient, of course, must be a suitable candidate for pneumothorax. Thoracoscopy must be carried out before a decision is made. If possible a release of the adhesions will be effected. If closed release cannot be done or if the adhesions are re-

leased incompletely the remaining adhesions are studied with open pneumonolysis in mind. The patient is acceptable for open pneumonolysis if the adhesions are not too extensive and numerous, if the area of lung adherent to the parietal or mediastinal pleura is not greater than the surface area of the operator's palm, and if there is no evidence of pleural exudate, tubercles, or pleuritis. The patient's physical condition must be good enough to withstand the operation. Open pneumonolysis is contraindicated if the conditions are contrary to those enumerated, namely: if extensive adhesions, large areas of lung adherence, pleuritis, pleural tubercles, or pleural exudates are present, or if the patient obviously could not withstand operation. True pleural effusions will contraindicate open operation but small transient effusions will not.

Perhaps the indications for open pneumonolysis have been held entirely too rigid. When thoracoscopy alone was done only 29.8 per cent of the cases were recommended for open operation. It is possible that more should have been recommended. Hope in 1937 subjected to open pneumonolysis only 7 of 220 patients who underwent a closed release of their adhesions or examination alone. However the rigid indications undoubtedly accounted for the absence of postoperative morbidity and mortality and the for the good end results. If the indications are to be relaxed at all it seems that one might accept more complicated adhesions and larger areas of adherence of the lung to the chest wall for operation. It does not seem feasible that one-half of the pleural surface can be denuded without complications. In such cases thoracoplasty surely would be indicated rather than open pneumonolysis.

From close observation it appears that patients tolerate the administration of general anesthesia better than local anesthesia. However, there is less difficulty with re-expansion under local anesthesia since the patient struggles on recovery from the general anesthesia.

The supine position with an anterior incision is used because there is less chance of aspirating bronchial secretions into the other lung.

The third interspace is selected for the incision. It gives the best exposure. One is sometimes tempted to use the second or fourth interspace, but if this course is followed the exposure is jeopardized. If the exposure is not adequate the adjacent costal cartilage may be divided. A division of the third costal cartilage allows more exposure in the apex, whereas division of the fourth costal cartilage permits greater exposure inferiorly. The breast is elevated superiorly. The skin, breast, fat, and pectoralis major muscle are raised as a single flap. This places the muscle incision inferior to the incision through the interspace.

The lung is always handled with great care in order to eliminate trauma. The adhesions are released in the endothoracic fascial plane, as pointed out by Eloesser and Carter. This step prevents injury to the lung. Much attention is given to hemostasis.

All bleeding points are controlled by suture ligatures of silk. No attempt is made to close the pleura or the intercostal space.

In this small series as in all other series in which pulmonary tuberculosis is treated disease in the contralateral lung reduces the chances for favorable end results. It appears that obliterative pleuritis occurs rather frequently after open pneumonolysis, but it is possible that the judicious use of oleothorax will control the obliterative pleuritis.

JOHN E. KIRKPATRICK, M D

Cory R. A. S.: Report of a Clinical Trial of Oxidized Gauze in 7 Thoracoplasties *J Thorac Surg.* 1946 15 267

After using oxidized gauze in 7 thoracoplasties the author draws the following conclusions:

Oxidized gauze (soluble cellulose) is a distinctly valuable addition to the hemostatic armamentarium. It provides, in an easily handled form a packing material which can be safely left in a wound with no fear of its remaining as an irritating or permanent foreign substance.

Its use in clean wounds does not delay the healing nor does it interfere with the strength of union of the tissues.

When soaked with blood it has no strength of fiber, but rapidly becomes a sticky mass which is admirably adapted to packing deep narrow cavities either in soft tissues or between raw surfaces of the bones.

The author expresses no opinion upon its suitability for use in contact with serous membranes nor does he attempt to say what effect it might have in the presence of deep sepsis in a surgical wound. However there is no doubt whatever of its value in thoracoplasty.

JOHN J. MALONEY, M D

Lindskog G. E. Bronchogenic Carcinoma. *Ann Surg.* 1946 124 667

In spite of the rapid advances, since 1933 in the technique of surgical resection for the eradication of primary pulmonary cancer the treatment of bronchogenic cancer is still disappointing and challenges further effort.

The author presents his experiences in the treatment of 100 consecutive cases of primary pulmonary cancer seen over a 5 year period ending December 1943.

Of the 100 patients, 82 were males a ratio of 4.5 males to 1 female. One patient was colored the expected racial distribution. The average was 54.8 years the youngest patient being 22 and the oldest above 70 years of age.

In 60 of the patients the first observed symptom was cough, pain in the chest, or a grippelike "cold." Six had early dyspnea, and 4 showed hemoptysis as an early complaint. Three had an acute pneumonic onset, 9 had vague complaints of weakness and weight loss, and 14 had initial symptoms related to metastases or extension of the tumor beyond the lung.

In 98 patients the average duration of symptoms prior to admission was 6.7 months. There was no significant difference in duration between operable and inoperable cases. The primary lesion was on the right in 51 cases and on the left side in 47 cases. The upper lobes and stem bronchi above the upper lobe orifice were involved in 69 per cent of the cases. In 2 cases the primary focus could not be determined.

Positive tissue diagnosis was obtained in 82 cases—in 77 living patients and in 5 at autopsy. In the remaining 18 the methods employed to give a positive biopsy failed or the patients refused to submit to the indicated procedures. These patients exhibited a typical clinical course and all subsequently died.

In 65 patients the condition was inoperable when first seen and 3 patients refused treatment. In 36 of these the carcinoma was proved by biopsy of metastases or by involvement of important nerves in 3 patients the carina or trachea was found to be invaded in 18 presumptive evidence of inoperability was present (roentgenographic or bronchoscopic evidence of mediastinal distortion), 7 patients were moribund and 1 patient had had radon treatment elsewhere, with no trace of the original lesion.

Surgical exploration was carried out in 32 cases. In 20 of these extension to hilar or mediastinal nodes or to the parietal pleura was observed. Local extension to the parietal pleura was not considered a contraindication to resection and a block resection of the locally involved area was carried out in several cases.

Of the 12 resections 10 pneumonectomies and 2 total upper lobectomies were carried out. Complications were observed in 20 of these: a putrid abscess in 1 patient, local parietal pleural extension in 3 patients, tuberculous hilar nodes in 1 patient, an obstructive pneumonitis with pneumococcal empyema in 1 and a massive pleural effusion without gross pleural involvement in 1. Invasion of the hilar (intratracheal) nodes was observed in 3 patients and contralateral metastasis was proved later in 1 patient.

The average age of the patients was 54 and the oldest patient was 68 years of age.

Thirty-eight patients who were given only diagnostic or symptomatic care survived for an average period of 5 months. Twenty-nine patients received high voltage roentgen therapy, radon implantation or both. All are dead after an average survival of 7.4 months. Treatment was of doubtful value as a means of prolonging life but was effective in producing relief from pain, decrease of dyspnea, improved aeration and bronchial drainage as well as in a psychotherapeutic way.

There were no operative deaths among the 20 patients in whom exploration without resection, had been carried out. Nine patients who had had no subsequent x-ray treatment survived for an average period of 8 months. Patients who had been treated by irradiation lived for an average period of 11.8 months.

Three patients died in the hospital following total pneumonectomy at 12, 42 and 80 days after oper-

think it necessary to give up artificial pneumothorax because of the occurrence of a bronchial stenosis. The decision depends rather on the course of the parenchymatous lesions and on whether any substitute treatment is available. There has been a great deal of discussion as to whether thoracoplasty should be performed on a cavity in the field of a stenotic bronchus. The question is not yet definitely settled. In the one case in which the authors at tempted such a thoracoplasty it was a failure but they do not believe the stenosis of the bronchus was entirely responsible for the failure. For the treatment of the stenosis itself powdering with cocaine or adrenalin followed by aspiration of the pus and intra tracheal instillation of antiseptic oil have been recommended. This treatment brought about improvement in 2 of the authors' cases. 1 patient developed intolerance for novocain, and in 1 case the patient died in spite of the treatment. Distention with bougies improves drainage but in the majority of cases does not bring about definite obliteration of the cavity. Surgical removal of the affected and bronchectatic lobes seems to be the logical treatment in spite of its severity. Although the mortality is high the patient is certain to die if not treated.

The question of whether the bronchial lesions are specifically tuberculous has been much discussed. In the 3 of the authors' cases in which careful histological examinations were made, no specific tuberculous lesions were observed.

ARTHUR G. MORROW, M.D.

Brantigan, O. C.: Open Pneumonolysis. *J. Thorac. Surg.* 946, 5 34.

The advances in medicine and surgery that favorably influence the results in open pneumonolysis are many. These advances, when applied clinically have eliminated most of the morbidity and mortality associated with past attempts at open pneumonolysis. Pneumothorax should not be carried out when the patient has a large tension cavity. Also when either fibrotic or tuberculous bronchial stenosis exists, pneumothorax should not be instituted nor should it be continued when atelectasis occurs. The necessity of doing open pneumonolysis is thus eliminated in this group of patients in whom complications are frequent and serious under pneumothorax therapy alone. Fewer patients need open pneumonolysis because the closed release of adhesions is highly effective. Thus when a patient is selected for an open operation no surprise or unexpected contraindications will be found when the pleural cavity is opened.

Three had an acute pneumonic onset, 9 had vague complaints of weakness and weight loss, and 14 had initial symptoms related to metastases or extension of the tumor beyond the lung.

In 98 patients the average duration of symptoms prior to admission was 6.7 months. There was no significant difference in duration between operable and inoperable cases. The primary lesion was on the right in 51 cases and on the left side in 47 cases. The upper lobes and stem bronchi above the upper lobe orifice were involved in 69 per cent of the cases. In 1 cases the primary focus could not be determined.

Positive tissue diagnosis was obtained in 82 cases—in 77 living patients and in 5 at autopsy. In the remaining 18 the methods employed to give a positive biopsy failed or the patients refused to submit to the indicated procedures. These patients exhibited a typical clinical course and all subsequently died.

In 65 patients the condition was inoperable when first seen and 3 patients refused treatment. In 36 of these the carcinoma was proved by biopsy of metastases or by involvement of important nerves in 3 patients the carina or trachea was found to be invaded in 18 presumptive evidence of inoperability was present (roentgenographic or bronchoscopic evidence of mediastinal distortion), 7 patients were moribund and 1 patient had had radon treatment elsewhere with no trace of the original lesion.

Surgical exploration was carried out in 32 cases. In 20 of these extension to hilar or mediastinal nodes or to the parietal pleura was observed. Local extension to the parietal pleura was not considered a contraindication to resection and a block resection of the locally involved area was carried out in several cases.

Of the 12 resections 10 pneumonectomies and 2 total upper lobectomies were carried out. Complications were observed in 20 of these: a putrid abscess in 1 patient, local parietal pleural extension in 3 patients, tuberculous hilar nodes in 1 patient, an obstructive pneumonitis with pneumococcal empyema in 1 and a massive pleural effusion without gross pleural involvement in 1 invasion of the hilar (intra tracheal) nodes was observed in 3 patients and contralateral metastases was proved later in 1 patient.

The average age of the patients was 54 and the oldest patient was 68 years of age.

Thirty-eight patients who were given only diagnostic or symptomatic care survived for an average period of 5 months. Twenty-nine patients received high voltage roentgen therapy, radon implantation or both. All are dead after an average survival of 7.4 months. Treatment was of doubtful value as a means of prolonging life but was effective in producing relief from pain, decrease of dyspnea, improved aeration and bronchial drainage as well as in a psychotherapeutic way.

There were no operative deaths among the 20 patients in whom exploration without resection had been carried out. Nine patients who had had no subsequent x-ray treatment survived for an average period of 8 months. Patients who had been treated by irradiation lived for an average period of 11.8 months.

Three patients died in the hospital following total pneumonectomy at 12, 42 and 80 days after oper-

ation. Six of the patients who had undergone resection died subsequently of metastases at intervals of from 3 to 26 months after operation.

Four patients are living—one 55 years after pneumonectomy for a squamous cell carcinoma, one, 45 years after pneumonectomy for a squamous cell carcinoma, and one, 25 years after lobectomy for a squamous cell carcinoma. One patient with anaplastic carcinoma of the mediastinum is alive and working 35 years after roentgen treatment. This last patient is the only one of the irradiated group in whom a lasting effect was obtained.

Two patients were submitted to pneumonectomy for solitary carcinoma metastases from the uterus and urinary tract with survivals of 24 and 5 months, respectively. The author did not include these cases in his statistical survey.

ROBERT R. BROOKS, M.D.

Carnes, O. J., Cesarelli, A., and Triccerri, F. R.: Surgical Treatment of Lung Cancer. Personal Experience (*Nuestra experiencia en el tratamiento quirúrgico del cáncer de pulmón*). *Praxis méd. argent.* 1946 33 61.

Between the end of 1943 and May 1946 107 patients with bronchogenic carcinoma were seen by the authors. Of this number 21 (21.4%) were considered suitable for exploration and 12 of the latter group were operable (57.1% of the cases explored). Eleven pneumonectomies and 1 lobectomy were done. There were 3 deaths (25%) from resection and 1 (4.76%) from an exploratory thoracotomy. A bronchopleural fistula occurred three times after resection, and empyema occurred in 25 per cent of the resected cases.

The contraindications to exploration are demonstrable metastases, laryngeal, cervical sympathetic, or diaphragmatic paralysis, hemorrhagic pleural effusion, skeletal involvement, and general debility of marked degree. The bronchoscopic signs of inoperability include involvement of the trachea and widening or fixation of the coryna.

The authors urge early diagnosis, including exploratory thoracotomy for the lesions peripherally located which are otherwise inaccessible for accurate diagnosis.

Twelve brief case reports and numerous illustrative roentgenograms are appended.

HIRAM T. LANGSTON, M.D.

Langer, L. and Bracco, A. N.: Segmental Pulmonary Resection. Its Indications (*Resecciones pulmonares segmentarias. Sus indicaciones*). *Praxis méd. argent.*, 1946 33 854.

This article is based on the experiences in the service of Richard H. Overholt of Boston. The technique of segmental resection is being described in an article by Overholt and Langer (in press) and is based on such interventions carried out on 32 patients with bronchiectasis (22), chronic abscess (4), tuberculosis (4), hamartoma (1), and myxoliposarcoma (1). No deaths occurred. The only significant

postoperative complication was empyema, which occurred in 15 per cent.

The authors review the concept of bronchopulmonary segmental arrangement, applying it to the intralobar areas. They adopt essentially the nomenclature of Huber and Jackson. Attention is called to the occurrence of interlobar vascular communications.

The segments are identified by bronchoscopy, bronchography, and at operation by occluding the corresponding bronchus and inflating or deflating the lung to indicate the segmental boundary in the parenchyma.

Segmental resection is useful for such conditions as bronchiectasis, chronic abscess, benign or undifferentiated tumors, and isolated metastatic neoplasms. Tuberculous, possibly simple bronchial cysts, localized emphysematous bullae, and even actinomycosis or hydatid cysts are suggested as other positions.

The segmental approach is useful in providing a means of eradicating the areas of disease without sacrificing normal functional lung; however, the caution is sounded that resection should be adequate by including all the involved areas, particularly in bronchiectasis. This conservation of lung may permit operations for multilobar involvement.

In tuberculosis the actual extent of disease is found at operation frequently precludes the distinction of resection to lobular segments, even though the procedure may be used in selected enormous lesions, tuberculosis, and in obtaining pneumonectomy when the disease has crossed an interlobar fissure.

The various indications are discussed, and case reports are given and illustrative roentgenograms and photographs are appended.

ESOPHAGUS AND MEDIASTINUM

White, M. L. Jr. and Birdsong, M.: Congenital Esophageal Atresia with Tracheoesophageal Fistula. *Surgery* 1946 20 548.

Although congenital atresia of the esophagus with tracheoesophageal fistula is not rare interest in the condition has recently received a stimulus from successful reports of operations for the previously uniformly fatal lesion. In 1929, Vogt summarized the variations of this anomaly in the following classification which is still widely accepted:

Type 1: complete absence of the esophagus (extremely rare); type 2: blind end to both upper and lower segments of the esophagus, with no tracheal communication from either segment (rare); type 3a: upper segment with tracheal communication and a blind lower segment (rare); type 3b: a blind upper segment and a communication between the lower segment and the trachea (common type); type 3c: communication of trachea with both upper and lower segments (rare). Thus there is only one type of type 1, i.e. type 3b which comprises about 90 per cent of the cases. Inasmuch as all attempts at

reconstructing a functional esophagus were failures until 1911 the report of a single case is thought justified

The patient was a white female infant. It was noticed at birth that there was much pharyngeal mucus which required aspiration and a marked but temporary laryngeal stridor. After 24 hours with every feeding the child would regurgitate and become somewhat cyanotic. Because of repeated regurgitation of everything taken by mouth a small catheter was passed into the esophagus on the morning of the fourth hospital day, and an obstruction was met about halfway down the length of the esophagus. The patient was taken to the x-ray department and 2 c.c. of iodized oil were injected into the esophagus by catheter. A complete atresia of the esophagus with a large bulbous upper segment extending as far down as the second dorsal vertebra was noted on fluoroscopy. Roentgenograms confirmed the fluoroscopic findings and also showed a large amount of gas in the stomach and intestinal tract. There was no evidence of pneumonia. The diagnosis of atresia of the upper portion of the esophagus with tracheoesophageal fistula of Vogt's type 3b was made and the patient was prepared for immediate operation.

Under local infiltration anesthesia the large upper blind pouch of the esophagus was easily identified and dissected free as was the lower segment also since it extended almost to the upper segment. Although much smaller in diameter it appeared to have a lumen adequate for anastomosis. The lower segment was attached to the trachea about $\frac{1}{4}$ cm. inferior to the upper segment. A tracheoesophageal fistula at this point was isolated after transfixion the ligatures were placed in the wall of the fistula close to the trachea the fistula was divided opening the lumen of the distal segment of the esophagus. The lumen of the upper segment was entered by amputating the bulbous tip of the upper segment.

A No. 8 French urethral catheter was passed into the stomach through the distal segment of the esophagus and its upper end was passed through the upper segment into the pharynx where it was retrieved by the anesthetist. The two ends of the esophagus could then be brought together over the catheter and held by traction sutures.

The diagnosis in the case reported was suspected when the child began to vomit her food immediately after ingestion, and in the intervals to eject continually a small amount of foamy saliva. Cyanosis especially at feeding time was also a noteworthy symptom. These are classic signs of the type 3b tracheoesophageal fistula.

There would seem to be no difficulty in choosing between the one-stage direct anastomosis and the indirect method from the point of view of functional end results. With the former the patient has, following a single procedure an esophagus approximating the normal with the latter he has, after a prolonged convalescence marked by multiple plastic operations, only a substitute for an esophagus. The data are as yet too incomplete to permit any positive

conclusions on the relative operative risk of the two primary procedures. There seems only one reason for the indirect approach namely an anatomic condition that will not permit direct anastomosis which unfortunately is frequently encountered.

This case is believed to be the fourth recorded case which did not include a supplementary gastrostomy. When gastrostomy can be avoided, the postoperative course is transformed from a difficult feeding and nursing problem of indefinite duration into one of parenteral maintenance for a few days followed permanently by normal oral feedings. Penicillin, by lessening the incidence of anastomotic leaks will probably decrease the need for gastrostomy.

The three important points in the postoperative care are the prevention of infection the control of body temperature and the maintenance of nutrition.

There should be the closest co-operation between the thoracic surgeon and the pediatrician in the handling of these cases.

STEPHEN A. ZIEMAN M.D.

James, R. M. Diverticula of the Lower Thoracic Esophagus. *Ann. Surg.* 1946 124 637

Diverticula of any portion of the thoracic esophagus are rare only 116 being reported in the literature up to 1934. This probably does not represent the true frequency of the disease. Improvement in roentgenological examinations of the esophagus will undoubtedly lead to more frequent recognition of this condition. Giant diverticula remain of interest.

Thoracic esophageal diverticula are described as of the traction or pulsion variety. The former are congenital and result from fixation of a point on the outer esophageal wall to an inflammatory tuberculous node

Fig. 1 (James) Exposure obtained (Courtesy of J. B. Lippincott Co.)

Fig. 2 (Jones) Diverticulum freed and held up by clamps.

Their wide open mouths seldom catch food and they are generally asymptomatic except for a rare perforation. The pulsion type are said to result from herniation of the mucous membrane through the muscular wall. The diverticula removed in this series had rather thick walls formed of squamous epithelium, submucosa, muscularis mucosa and a layer of fibrous tissue. In all cases there was marked infiltration of inflammatory cells in the submucosal area.

The etiology of these diverticula is unknown. Some are associated with cardiospasm and are regarded as a rare complication of that condition. Some additional factor either congenital weakness or degenerative change in the esophageal wall may be responsible.

Barrett has suggested a third type of esophageal diverticulum, the traction-pulsion in which a combination of etiologic factors is said to exist.

The outstanding symptom is difficulty in swallowing. It may be first noted with liquids or be more troublesome with solids. Substernal pain sometimes referred to the interscapular region is nearly always present. Vomiting or regurgitation occurred in all cases. Loss of appetite, weight loss and sometimes extreme dehydration may follow. The symptoms seem to occur in episodes with the patient free of discomfort for long periods.

Diagnosis is based on the clinical history and demonstration of a diverticulum on barium study of the esophagus. In 2 cases a fluid level on the plain chest roentgenogram led to discovery of the lesion.

Diverticula discovered on routine examination need treatment. Those associated with symptoms should be treated surgically.

Fig. 3. Method of excision and suture.

The symptoms probably are initiated at times by an inflammatory swelling. Patients with large diverticula should be encouraged to be operated on while still in good condition. There is danger of stenosis, perforation and hemorrhage. When the operation is delayed too long, the patient becomes seriously ill with malnutrition and dehydration and the danger of operation is much increased.

Preoperative malnutrition and dehydration should be corrected by continuous feeding through a duodenal tube. The esophagus and diverticulum should be washed out with a tube on several occasions for 24 hours preoperatively. The tube in the esophagus at operation aids in identification of the esophagus and diverticulum. It is used after operation for aspiration of air and fluid from the stomach for the first day or two and later for feeding. Swallowing is permitted after the fifth day. Intratracheal closed anesthesia is necessary because of the danger of opening into the right pleural cavity during the dissection. Blood should be replaced as necessary.

A posterolateral approach through the seventh or eighth intercostal space is satisfactory. The mediastinal pleura is incised for 3 inches in the region of the diverticulum and the esophagus and diverticulum are gently isolated and lifted forward on tapes (Fig. 1). The sac usually arises from the posterior aspect of the esophagus and joins it by a neck several centimeters in diameter (Fig. 2). Then 3 Kocher forceps are placed across the neck of the diverticulum which is then divided with a cautery between the 2 distal clamps. The second clamp is removed and the

fringe of tissue left is oversewn with a running suture of chromic catgut on an atraumatic needle. The third clamp is removed and the first layer of sutures is invaginated with a row of Lambert sutures (Fig. 3). There is no encroachment on the lumen. The divided mediastinal pleura is sutured behind the isolated portion of the esophagus in order that infection if it should occur will involve the pleural cavity rather than the mediastinum. The chest is closed with a water sealed intercostal drain to the site of operation. The author suggests the use of penicillin post-operatively for from 5 to 7 days to lessen the danger of local or pulmonary complications.

The author then gives the case reports of 6 cases of diverticula of the thoracic esophagus. The first 4 were operated on without a mortality. The patients had complete relief of symptoms. Preoperative and postoperative roentgenograms are shown.

ROBERT R. BIGZLOW M.D.

Sweet, R. H.: Carcinoma of the Midthoracic Esophagus. *Ann. Surg.* 1946 124 653

Any operative treatment for carcinoma of the esophagus should be undertaken with the aim of prolonging life, effecting a possible cure, and relieving the distressing obstruction produced by the growth.

Until recently the Torek operation was the only available method of removing a carcinoma of the midesophagus. The Torek operation fails to provide for removal of the subdiaphragmatic pericardial nodes and the left gastric nodes both of which were involved by tumor in 50 per cent of the author's series of 32 cases. With the Torek operation the principle of cancer therapy (wide excision of the primary tumor and of as many of the regional lymph nodes as possible) is violated. It fails to provide satisfactory palliation as has been shown in the author's report of 14 cases. All but 1 of the patients died of recurrence or metastases and 10 patients died before the external esophagus was completed.

A satisfactory technique has been developed for radical resection of the local disease and of at least 3 of the 4 groups of regional nodes usually invaded. The author states that use of the method offers greater promise of a cure and in addition the intrathoracic esophagogastric anastomosis permits the patient to swallow normally. Because of the palliation afforded by this procedure it is believed to be far superior to the Torek operation.

The author describes his technique for esophagotomy with high intrathoracic esophagogastric anastomosis. Under intratracheal ether-oxygen anesthesia an incision is made over the entire length of the eighth rib which is resected. Often one or more ribs posteriorly must be divided to provide access to a high tumor or to perform a high anastomosis.

First the resectability of the growth must be determined by incising the mediastinal pleura and beginning the dissection anterior to the esophagus. Here invasion of the left main bronchus, extensive involvement of the region around the inferior pulmonary vein or fixation to the aorta may make the

tumor inoperable. If adhesions to these structures can be divided dissection of the posterior attachments is begun. In the author's cases this procedure was delayed in order to avoid interference with the blood supply of the midesophagus as the result of dividing one or more of the esophageal arteries arising from the aorta. After the posterior attachments are divided the tumor must be freed from the right mediastinal pleural reflection. Sometimes a portion of this pleura must be excised. This was done without complication in 3 of the 32 cases reported. With the closed method of anesthesia the lung is kept expanded, and the chest is closed without any attempt to repair the pleural defect. In a few cases a small portion of the adjacent lower lobe of the right lung (if it is fixed to the growth) must be removed. The lung defect is closed with a continuous suture of catgut on an atraumatic needle.

After the esophagus is dissected free from the level of the aortic arch downwards the diaphragm is opened from the esophageal hiatus to the costal margin. The phrenic nerve is crushed for diaphragm immobilization. The upper two-thirds or more of the stomach is then freed in order to allow the fundus to be brought to a high level in the chest for anastomosis. The gastroligament is divided and the left gastropiploic vessels and the vasa brevia are cut and tied. The spleen is retracted and the gastrosplenic omentum is divided as far as the pylorus being careful to avoid injury to the right gastropiploic vessels. The attachments of the cardia and lower esophagus, including branches of the superior suprarenal, inferior phrenic and the pericardiophrenic vessels, are then cut. The left gastric artery is cut and tied close to its origin from the celiac axis and then the stomach fundus can be placed without difficulty in the apex of the chest.

The stomach is divided between the clamps at the cardia with care to remove the lymph nodes near the lower esophagus, cardia and left gastric vessels. The distal portion is inverted by means of two layers of continuous sutures of fine chromic catgut reinforced with a layer of interrupted silk sutures. A rubber glove is tied over the lower end of the esophagus. After the stomach is mobilized, the mediastinal pleura is incised and the esophagus in the superior mediastinum is freed by blunt dissection.

Whenever possible, dissection behind and above the arch of the aorta is avoided, and the anastomosis is performed just below the arch.

At a high level on the fundus of the stomach a circular incision of appropriate size is made through the serosal and muscular coats. A suitable site for the anastomosis is chosen several centimeters above the upper limits of the growth and an outer layer of mattress sutures comprising the first layer of the posterior half of the anastomosis is placed and tied. A Wertheim clamp is placed on the esophagus several centimeters distal to the site of the anastomosis and the muscularis of the posterior esophageal wall is incised. The resulting muscle edge of the esophagus is sutured to the muscle edge of the stomach.

The posterior half of the esophageal mucosa is then incised and the circular portion of the stomach out lined by the initial incision is excised. The gastric contents are aspirated. The posterior layer of mucosal sutures is then applied. With bent blade scissors the anterior wall of the esophagus is incised and the specimen is removed. With the use of fine silk throughout the anterior three layers of the anastomosis are completed. A series of interrupted sutures are used to fasten the stomach to the parietal pleura to relieve pull on the anastomosis. The diaphragm edges are fastened to the pyloric antrum and approximated. Penicillin (50 000 units) is injected half in the thoracic and half in the abdominal cavity before closure. The incision is closed anatomically with silk sutures. A catheter for closed suction drainage is brought out through a stab wound one interspace lower posteriorly.

At completion of the operation the stomach is dependent for its blood supply on the right gastric and the right gastroepiploic arteries. The continuous arcades of the gastroepiploic arteries, the anastomosis between the right and left gastrics, and the inter communicating branches in the stomach wall are essential for nutrition of the anastomosis site hence great care in handling the stomach throughout the entire operation must be exercised. The esophagus has a segmental blood supply. If the anastomosis can be made below the arch the nutrition at the cut end will be adequate because of the small arteries arising from the arch and bronchial arteries. If the superior esophagus must be mobilized its only blood supply arises from the inferior thyroid artery. Therefore the esophagus when pulled anterior to the arch of the aorta must be divided at a high level within the chest in order to avoid necrosis at the cut end. Even though it is more difficult from a technical standpoint to do this, it may mean the difference between success and failure of the operation.

The thoracic duct was tied and divided in 3 of the cases with no ill effects. In a fourth case the duct was injured but not tied. This patient died of a chylothorax.

To avoid stricture at the anastomosis the author recommends (1) avoidance of using crushing clamps on either the gastric or esophageal side, (2) the use of knife and scissors to cut the esophagus and stomach instead of cautery or chemical caustics, and (3) the use of fine interrupted sutures instead of constricting running sutures. A circular opening in the stomach wall for the anastomosis may also be of importance.

During 1944 and 1945 66 patients with mid thoracic carcinoma were seen and 41 were operated on. In 9 of these resection was impossible. Thirty two (48.5%) had resections with high intrathoracic esophagogastric anastomosis. The high resectability is due to the feeling that the growth should be removed whenever possible, for palliative reasons. Of the 9 patients in whom resection was impossible 8 recovered and left the hospital only to die a few months later. The ninth patient died soon after operation, of widespread lymphatic invasion.

Of the resected cases one-half of the patients were over 65 years of age. In 14 of the 32 patients it was impossible to do the anastomosis below the arch of the aorta. Complications developed in 13 patients only 3 of whom were in the group with anastomosis below the arch. There were 2 postoperative deaths as compared to 6 in the group with the anastomosis above the arch.

Cardiac disorders caused the death of 5 patients, only one of these being in the subaortic anastomosis group. Three patients developed sepsis—empyema, mediastinitis and a wound infection of *Staphylococcus aureus* which responded to penicillin. Chylothorax developed in 2 patients. In 1 the condition came on rapidly and was fatal in the other. It developed slowly and the patient died several months later of metastases. One patient developed sublethal pulmonary embolus and recovered after superficial femoral vein ligation. One patient died after a pulmonary atelectasis and failed to respond to treatment. One patient recovered from a trivial surgical shock. ROBERT R. BARNER, M.D.

MISCELLANEOUS

Robertson, R.: Crushing Injuries of the Chest. *J. Thorac. Surg.* 1946, 15, 324.

Crushing injuries of the chest are commonly encountered in civilian practice and for the most part are not adequately treated. They may cause shock and death from the following disturbances of the delicately balanced cardiorespiratory function: (1) hemorrhage, (2) cardiac tamponade, (3) respiratory failure (mechanical asphyxia) and (4) acute pulmonary edema.

In the treatment of crushing injuries of the chest it is essential to diagnose the pathological condition accurately and to understand clearly its effect on the physiology of the respiration and circulation. A crushing injury of the chest may fracture numerous ribs and thereby cause paradoxical respiration, i.e., a flapping chest wall. A fractured rib may puncture the lung or blood vessels or even in the absence of rib fractures, a sudden crushing injury may tear these structures. The following pathological conditions should be kept in mind: (1) airway obstruction with blood, (2) flapping chest wall, (3) hemothorax, (4) tension pneumothorax, (5) massive atelectasis, (6) mediastinal hematoma, (7) mediastinal emphysema, (8) hemopericardium, (9) diaphragmatic hernia, (10) acute gastric dilatation, and (11) air embolism.

Oxygen should be administered immediately at the rate of from 8 to 10 liters per minute, even before cyanosis develops. The first signs of anoxia, rapid pulse, dyspnea and restlessness may appear sometime before cyanosis develops. An immediate portable x-ray examination should be ordered. Prompt interruption of treatment for although the diagnosis will usually be clear on physical examination, x-ray cases will be most misleading and x-ray view is lifesaving.

Blood obstructing the airway should be removed by suction with a catheter passed through the nose into the bronchus.

A flapping chest wall with painful and paradoxical respiration can be relieved by adhesive strapping encircling the chest. Morphine may be given intravenously with caution to relieve pain. Depression of the cough reflex is not a disadvantage in the early treatment but tends to prevent further hemorrhage. Loss of blood is replaced by transfusions with large quantities of citrated blood, or if this is not avail-able serum.

A hemothorax should not be aspirated for 3 or 4 days, or until danger of intrapulmonary hemorrhage is over when torn pulmonary vessels have had sufficient time to become firmly thrombosed. The hydrostatic pressure of large quantities of blood in the thorax may cause cardiac tamponade but on the other hand it will tend to stop bleeding from the lung and the chest wall therefore if there are signs of cardiac tamponade aspiration should be only in amounts sufficient to relieve the symptoms and the lung should be replaced with air sufficient to keep it collapsed.

Aspiration must be persistent until the lung is completely and permanently re-expanded. Bronchial secretions or hemorrhage should be removed by aspiration rather than hard coughing. A diaphragmatic hernia is almost the only indication for immediate thoracotomy in crushing injuries of the chest. In every general hospital a team trained and equipped to treat crushing wounds of the chest would save many lives.

STEPHEN A. ZIEGLER, M.D.

Letts, R. H. The Initial Surgery of Thoraco-abdominal War Injuries. *J. Thorac. Surg.* 1946 15: 349.

The term thoracoabdominal wound denotes injury to the thorax and abdomen by the same missile. Such a wound necessitates actual penetration through the diaphragm, or transmission of sufficient force to produce injury in the other serous cavity. The vast majority of thoracoabdominal war injuries are due to missiles actually traversing the diaphragm. Casualties with separate wounds of the abdomen and thorax present a different problem and these are better termed combined thoracic and abdominal injuries. The discussion is limited to true thoraco-abdominal wounds.

A working diagnosis is readily apparent in the majority of war wounds including thoracoabdominal injuries. A thorough inspection of all surfaces of the thorax and abdomen both anteriorly and posteriorly for wounds of entrance or exit plus the usual examination and roentgenological procedures is sufficient in most cases. The pleura can be assumed with reasonable accuracy, to follow the outline of the periphery of the ribs and costal cartilages. Any missile passing through the area from the level of the twelfth rib posteriorly to the level of the fourth rib anteriorly (on expiration) may or may not

have entered both the pleural and peritoneal cavities. A large number of soldiers are wounded while lying prone, and the increased abdominal pressure further raises the upper limit of the diaphragm.

Resuscitative methods and proper preoperative care are of utmost importance to both the thoracic and abdominal casualty. If the wound is a thoraco-abdominal one certain concessions may have to be made that are not ideal from one or the other viewpoint. Thoracic physiology should be restored to as nearly normal as possible before operation and as length of time this takes within limits is unimportant from the thoracic standpoint. Time is of great importance in cases of abdominal injury. It is therefore often necessary to treat patients with a thoracoabdominal injury somewhat differently than patients with either straight thoracic or abdominal conditions are treated. Replacement therapy with blood plasma and electrolytes can be used quite freely for abdominal cases but there is some danger of overloading the already deranged cardiorespiratory system of the thoracic casualty.

Two other factors need to be mentioned in regard to resuscitative measures for thoracoabdominal cases. The first factor is that of the influence of disturbed cardiorespiratory physiology on the production and prolongation of shock. The second is a similar influence due to severe peritoneal or pleural cavity contamination. The main causes of a disturbed cardiorespiratory balance in the recently injured man are as follows. The presence of blood and/or air in the pleural cavity with diminution of the functioning pulmonary parenchyma, the presence of large pulmonary hematomas, the splinting effect of pain from an injured thoracic cage and excessive blood or mucus in the tracheobronchial airway.

Shock therapy must be continued during and after operation. It is therefore wise to insert a needle or cannula in the saphenous vein preoperatively because it is not as likely to become dislodged by the necessary manipulations of the patient as if it were in a vein of the arm.

A Levine tube for stomach decompression is best inserted soon after admission as many patients have surprising degrees of gastric dilatation which by elevating their diaphragm further hampers adequate oxygenation. Also the period of time since the ingestion of food is not a good criterion of the amount of material in the stomach since a large residue is often present many hours after eating. This may be due to pylorospasm or lessened gastric motility from the nervous tension of battle.

Endotracheal oxygen-ether by the closed method was the author's choice of anesthesia. Periodic aspirations of material from the trachea and bronchi were essential. Positive pressure was useful to expand the lung periodically during operation and to encourage pulmonary expansion at the end of operation especially if the thorax was closed without drainage.

In selecting the operative approach, prime consideration should be given to the expected intrathoracic

and intra-abdominal damage. There are distinct advantages to the thoracic approach for operations that can be done from above. These can be enumerated briefly as follows. It facilitates repair of some upper abdominal organs such as the spleen and upper portion of the stomach. Colostomies can be done when indicated through a muscle splitting incision at a greater distance from the main incision than is possible through the abdominal exposure. Patients can be carried in a lighter plane of anesthesia as abdominal relaxation is not necessary. The diaphragm can be more easily and satisfactorily repaired from above than from below. In patients with marked pleural contamination the pleural cavity can be thoroughly washed out with saline solution to reduce the degree of infection. The postoperative course is smoother following thoracotomy than it is after a celiotomy since there is less pain and less tendency toward pulmonary complications.

There are certain limiting factors to the transdiaphragmatic approach. Lesions of the terminal 18 inches of the small bowel and the colon except for the transverse splenic flexure and proximal descending portions usually cannot be exposed adequately from above. For cases with minimal thoracic involvement the abdominal approach prevents entrance to both the abdominal and the pleural cavities. It should be pointed out, however, that any except the smallest hole in the diaphragm constitutes a sucking wound of the thorax when the abdomen is open just as much as does a hole through the thoracic cage. Not infrequently patients will develop pulmonary embarrassment from the aspiration of air through the hole in the diaphragm while abdominal repair is being completed. If this condition is permitted to continue and is unrecognized serious results may follow. Also bowel or stomach contents in the peritoneal space may be aspirated into the pleural cavity. Diaphragmatic repair instead of being relegated to the conclusion of the operative procedure should be the first step when using the abdominal approach.

Correction of cardiorespiratory imbalance is the most important phase of the preoperative preparation of casualties with thoracoabdominal injuries. Thoracentesis, intercostal nerve block and maintenance of a free airway are the three essentials of so doing.

The diagnosis of thoracoabdominal injury is often difficult if the wound is in the region of the diaphragmatic sulci. Exploration should be done in any case about which there is reasonable suspicion as to pleural involvement.

The mortality rate in thoracoabdominal injuries is directly proportional to the severity of the wound. The rate increases progressively as the number of injured abdominal organs rises. Likewise right-sided injuries do better than left-sided ones since in the former the liver is frequently the only abdominal organ involved.

In the series of 903 thoracoabdominal injuries treated by the surgical teams of the Second Auxiliary

Surgical Group the overall mortality was 27.1 per cent. For the severely wounded thoracoabdominal casualty surviving the first postoperative day the syndrome of "post-traumatic uremia" is no longer a hazard. In a series of 48 cases, with 11 deaths of the fatalities were due to this syndrome.

It has been demonstrated that more patients with thoracoabdominal wounds die of pulmonary complications than succumb to complications within the peritoneal cavity. This indicates that reducing the incidence of pulmonary complications in the immediate postoperative period by careful attention to securing a completely expanded lung against an intact chest wall, and the maintenance of a free airway should result in a lowering of the mortality rate for this group of casualties.

JOHN E. KIRKPATRICK, M.D.

Minkin, S. L.: The Causes of and Indications for Re-Operation Following Gunshot Wounds of the Chest. *Fractures*, Dec. 1945, No. 4, 131.

The author's experience extends over 600 cases of perforating wounds of the chest seen in craniocervical hospitals deep behind the front lines. These cases had already been operated upon at least once.

In reviewing the indications for reoperation, the author cites in the first instance an inadequate primary operation. Reoperation was done 6 times in cases in which the first operation had been a Connors operation, and 7 in which the first was a Heller operation. In these patients the condition was too far advanced when the first operation was instituted. Nine patients underwent a secondary operation following a restricted Schede operation which had not been carried out thoroughly and extensively enough because the patient's general condition at operation forbade a more radical procedure, or the first surgeon had failed to appreciate the requirements of the individual case. Five of these proved to be the author's own patients.

The second principal cause of nonhealing wounds and fistulas is the presence of isolated cavities, often multiple, which are connected by narrow fistulous tracts with the main cavity for which the patient was originally operated upon. These are not always detectable even by roentgenological methods. The best method to avoid missing such a condition is a careful probing of the original cavity.

A third indication of re-operation is the presence in the pleural cavity of a foreign body. Foreign substances gain access to the cavity either at the time of injury or operation or during the changing of the dressings (drains, tampons, needles). Re-operation for this cause was performed by the author in 8 instances. In 4 of these the roentgenological examination enabled a preoperative diagnosis of the condition. In the other 4 the foreign material was found by chance during the operation itself (bits of rubber glove, pieces of tampon). In 3 other cases, in addition to these 8, the foreign body lay outside of the pleural cavity in a sinus. 11 of these patients the body was lodged in the peripheral tissues of the lung and par-

tially protruded into the pleura. In all of these patients the secondary operation resulted in immediate cessation of the suppurative manifestations and rapid healing. Such cases demand careful palpation with the finger of the pleural cavity.

A fourth indication is a localized osteomyelitis of the rib. In these cases the surgical technique employed must cover three possibilities. In the first instance in which the fistula does not connect with the pleural cavity the technique does not differ from that for osteomyelitis in any other bone of the body, but when the process connects with a residual pleural pus pocket the procedure should be radical with wide exposure of the affected rib and cavity. The third possibility is the coexistence of costal osteomyelitis and a pleural cavity which are not connected but nevertheless mutually influence each other.

When the osteomyelitic process is located in the cartilage of the rib roentgenography offers the best means of revealing the condition.

As a fifth cause of nonhealing of wounds and fistulas the author admits the possibility of secondary epithelization of the fistulous tract as described by Eggers. The author does not mention any experience with this condition in his material but nevertheless emphasizes thorough removal of the entire fistulous tract at operation and early removal of drains as prophylactic measures. In general, the author prefers to err on the side of premature suppression of drainage especially of the Bulau type of closed drainage, as soon as the discharge of pus has ceased

and the roentgenological examination shows the absence of fluid in the cavity being drained. The drain may be reintroduced if manifestations of fluid retention develop.

As a sixth indication for re-operation the author describes a condition of localized thickening and cicatrization of the parietal pleura. In 4 of his patients such an area seemed to harbor infection, and wide exposure with removal of the entire anterior wall of the cavity or at least localized removal of the thickened area, resulted in prompt cessation of the symptoms and complete healing.

As a seventh indication of nonhealing of wounds and fistulas of the chest is cited the presence of lung abscess and bronchial fistula. These cases will be the subject of a detailed report later on; here the author merely mentions their marked tendency toward spontaneous healing. In only 4 of the 26 patients in this group the bronchial fistulas required a secondary operation.

An eighth indication for re-operation is given as the association of a perforating wound of the chest with a pulmonary tuberculous process. In all of the author's patients with this association the condition had been recognized too late to prevent the fatal termination. The association is merely mentioned in order to emphasize the necessity of early diagnosis and a primary operative procedure (removal of the hemothorax) of the immediate institution of hygienic and dietary measures, and the avoidance if possible of a secondary operative procedure.

JOHN W. BRENNAN, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Ivanissevich, O., and Defazio, F.: Gelatinous Disease of the Peritoneum (*Enfermedad gelatinosa del peritoneo*). *Sem med B AJ* 1946, 53: 554.

A case of pseudomyxoma of the peritoneum also called Pean's disease or gelatinous disease of the peritoneum is reported by the authors. A man 43 years old noticed a gradual increase in the size of his abdomen. Nine months after the onset of the disease an operation was performed and 7 liters of fluid were withdrawn from the abdomen. The examination 6 months after the operation revealed an enormous enlargement of the abdomen which was slightly painful to palpation. Rather large nodules could be palpated through the abdominal wall. Paracentesis furnished fluid containing lymphocytes and endothelial cells. A tentative diagnosis of hydatidosis was made. The operation disclosed microcystic tumor formations, resembling grapes, scattered all over the parietal and visceral peritoneum and omentum. A large gelatinous mass was present in the abdominal cavity. The histological examination of a biopsy specimen established the diagnosis of pseudomyxoma.

Three months after the last operation the patient was readmitted and appendectomy was performed. The appendix was dilated and surrounded by cysts.

Three months later the patient was again admitted to the hospital with complaints of fatigue and progressive weakness. At operation it was found that the pseudomyxomatous nodules assumed the character of a neoplasm. It was impossible to remove all of the tumor formations. The histological examination showed fibrous bands and cavities lined with cylindrical partially calcified epithelium. Eleven months later a small hard, painless tumor was found in the left axilla. Histological examination of this tumor established the diagnosis of metastasis of a mucoid adenocarcinoma.

Eleven months after the last operation the patient was found in a stage of cachexia with a markedly enlarged abdomen. Roentgenogram showed metastases in the lungs.

The author concludes from his observation that pseudomyxoma of the peritoneum should be considered as a cancer originating from cylindrical epithelium. Such formations may develop from a pseudomucinous tumor of the ovary, intestinal diverticulum or mucoid disease of the appendix.

JOSEPH K. NARAY, M.D.

GASTROINTESTINAL TRACT

Allen, A. W., and Welch, C. E.: Subtotal Gastrectomy for Duodenal Ulcer. *Ann Surg* 1946, 124: 683.

This study is a critical analysis of subtotal gastrectomy for duodenal ulcer performed on 195 pa-

tients. The series includes follow-up studies in 191 cases. The three main indications mentioned are cicatricial stenosis, massive hemorrhage, and intractable pain.

In discussing cicatricial stenosis, the authors point out that many ulcer patients become temporarily obstructed during acute exacerbations. However, these have a more sudden onset of symptoms and enter the hospital in a good state of nutrition. Such patients always respond to gastric drainage and intravenous therapy within a week or 10 days. Gastric resection is performed for the cicatricial type of stenosis rather than gastroenterostomy or pyloroplasty even in elderly patients.

In patients beyond the fifth decade an actively bleeding ulcer does not respond to conservative therapy in one-third of the cases. The younger patients nearly always recover regardless of treatment, whereas a large percentage of the older patients continue to succumb unless subjected to operation early during their bleeding period.

Intractable pain is an indication for surgery in many patients who, if they were in a better economic or intellectual status, might well have continued on conservative measures. However, there are many intelligent patients who will fall into this category.

Technically, the patients who are to undergo gastrectomy are divided into four main groups by the authors. Group I includes the cases in which part or all of the ulcer scar was used in the closure of the duodenum. There were 139 cases in this group with a mortality of 5.2 per cent. Four of the 7 deaths were due to late massive hemorrhage.

Group II included the cases in which the ulcer was far enough distal to the pylorus to allow a transection of the duodenum above the ulcer and leave room for an adequate closure. In these cases removal of the ulcer might have led to disturbance of the bile ducts. There were only 18 patients in this group with 2 deaths, a mortality of 11.2 per cent.

In the 27 patients in Group III, the authors performed transection of the antrum proximal to the pylorus with excision of the mucosa from this segment in addition to a generous gastric resection. There were 2 poor results in this group. This procedure has lost favor even in the eyes of Finsterer who suggested the operation originally.

In Group IV there were only 3 patients. It included those patients operated upon in two stages as advocated by McKittrick. The two-stage operation has all the disadvantages of any graded surgical procedure. The authors believe that this plan should be more widely adopted, since the 6-week interval between the two stages gives the inflammatory reaction about the ulcer a chance to heal. At the first stage prepyloric gastrectomy with anastomosis is done, the duodenal stump is dealt with at the second stage.

Transverse incisions were used in patients having a flaring costal angle and in those with low lying stomachs. There were 24 nonfatal complications of which were bland thrombi with pulmonary embolism. In 5 cases there was stomal obstruction and in 3 atelectasis.

Persistent gastrointestinal symptoms of some degree will occur in about one-third of the cases. The most frequent residual symptom is the inability to eat a full meal and discomfort gas or nausea after eating. Less common but more troublesome are the symptoms of the dumping stomach. Such patients have a sense of exhaustion or weakness after meals and occasionally have a rapid pulse perspiration, or vertigo followed by diarrhea or lower abdominal cramps. These symptoms are often alleviated by dietary measures and can be benefited by a high-protein low fat diet. A considerable number of patients gain weight whereas a larger percentage have difficulty acquiring their normal weight and cannot eat enough to gain while carrying on their work. The average weight loss is nearly twice as high in women as it is in men. Patients who have been operated upon for obstructions lose the least weight whereas those in which resection was done for pain or bleeding lose the most. It is interesting to note that postoperative results are better in women than in men.

The authors are convinced that posterior short loop anastomosis is preferable to antecolic anastomosis. It has been shown experimentally that each additional few centimeters of the small intestine proximal to the anastomosis add to the incidence of anastomotic ulcer. There were only 3 anastomotic ulcers in the followed-up series.

In the discussion Dragstedt stated that the authors results bear out his contention that removal of so important a digestive organ as the stomach has a profound effect on the nutritive status of the patient and he believes that eventually resection of the vagus nerves will supplant gastric resection in most instances of ulcer with intractable pain.

HAROLD LAUFMAN, M.D.

Hellner H: Concerning the Diminution in Size of the Niche in Cancer of the Ventricle. A Difficulty in the Differential Diagnosis between Carcinoma and Ulcer of the Ventricle. (Ueber die Grössenabnahme der Nische bei Carcinoma ventriculi) *Ada radiol* Stockh. 1946 27 153.

The differential diagnosis between juxtaepiloric cancer and ulcer often cannot be made in a single roentgen examination. The size of the niche is not a valid basis for distinction since an ulcer may have a large crater and a cancer a small one. Unless the medical therapy is indicated with subsequent x-ray follow-up. Generally a diminution in size of the crater with medical treatment is thought to rule out cancer and justify the continuation of a conservative regimen. However the author gives an account of 4

cases in which a definite diminution in size of the niche was observed but at operation all of the lesions were proved to be cancer. In 3 cases there was a disappearance of the subjective symptoms along with the diminution in size of the crater.

In Europe it has not been emphasized that shrinkage in the size of an ulcer crater does not rule out cancer. The author cites numerous American writers who have pointed out that the niche in gastric carcinoma may become smaller on a medical regimen. A number of artefacts are discussed which might make a crater seem smaller in one examination than in a previous one. True decrease in size may also occur in gastric malignancy. If the lesion is an ulcer which has undergone malignant degeneration in one portion medical treatment can still cause healing of the nonmalignant portion. If an ulceration of a primary cancer is involved decrease in size may occur by growth of the cancer tissue into the crater by generalized contraction of the stomach in scirrhus cancer or because the crater is a true peptic ulcer developing in a carcinoma and responds like any other ulcer to medical therapy.

The author concludes that a roentgen diagnosis of benign ulcer in the ventricle requires complete disappearance of the niche with nothing remaining in the place to suggest carcinomatous infiltration.

THEODORE B. MANSKILL, M.D.

Zinninger M M: The Surgical Treatment of Bleeding Peptic Ulcer *Surg Clin N America* 1946 25 1140

The management of severe hemorrhage from peptic ulcer is difficult to standardize. It is generally agreed that a patient who has had severe recurrent hemorrhage should be treated by operation during an interval after bleeding has ceased and the effects of blood loss have been corrected. However many patients bleed to death during a hemorrhagic episode. If one could determine early which patients would respond to conservative therapy and which would continue to bleed one could operate on those in the latter group early in the course of bleeding and reduce the number of deaths from hemorrhage.

When a patient vomits blood and presents the symptoms and signs of bleeding into the upper gastrointestinal tract one must consider the likelihood of ulcer and attempt to elicit a history suggestive of this lesion. Other conditions which may simulate bleeding ulcer are esophageal varices secondary to hepatic cirrhosis or portal hypertension, secondary gastritis bleeding tumor hemorrhagic disease, and aneurysm with erosion into the esophagus or duodenum.

The following studies are helpful in establishing the diagnosis: routine blood studies, determination of the prothrombin time and blood urea nitrogen, fluoroscopy for evidence of aneurysm attempts to demonstrate esophageal varices by theValsalva technique and roentgenological study of the stomach and duodenum with barium by the Hampton technique.

If the presence of peptic ulcer is established the advisability of early surgery must be considered. If bleeding is moderate and appears to cease promptly the patient should be managed by nonoperative measures.

If the bleeding is massive, continuous, or recurrent and particularly if the patient is past 60 years of age, operation should be performed after adequate blood replacement therapy. The progress of bleeding may be estimated by clinical examination and by frequent blood pressure, red cell, hemoglobin, and hematocrit determinations. Digestion of blood in the gastrointestinal tract produces an elevation of the blood urea nitrogen and affords an excellent guide to the amount of blood loss and to the continuation or recurrence of hemorrhage.

The author's plan for the management of patients with bleeding peptic ulcer is described in detail. Usually these patients may be placed in one of the following groups:

1. Patients with known chronic peptic ulcer who bleed seriously while under treatment. These should be operated upon promptly.

2. Patients with duodenal ulcer who have been operated upon previously. These will usually bleed from a gastrojejunal ulcer and will usually respond to nonoperative treatment. If bleeding persists operation may become necessary and may be quite complicated and difficult.

3. Patients in whom the source of bleeding cannot be definitely established. These will require thorough study and much caution in the selection of therapy.

4. Patients with perforation, obstruction, or other complications in addition to hemorrhage. These require prompt operation.

5. Patients in any of the groups given who suffer repeated severe hemorrhages. These may require surgical treatment unless one can definitely establish that the bleeding is due to some condition other than ulcer.

The type of operative procedure must be selected for each case. The patient is brought to the operating room while receiving a transfusion. A tube is placed in the stomach and anesthesia is induced by intratracheal administration of cyclopropane and oxygen with or without ether. A transverse upper abdominal incision is preferred. Excision of the ulcer with partial gastrectomy is the method of choice, but the condition of the patient may not permit a procedure of this magnitude. Ligation of the vessels from outside the stomach may control bleeding from a gastric ulcer but a duodenal ulcer will require duodenotomy with transfixation suture of the ulcer bed around the bleeding site, followed by closure of the duodenum or by resection. Bleeding from a diverticulum or neoplasm usually requires resection of the offending lesion.

Four brief case reports illustrate some of the more difficult problems encountered in the management of these patients with bleeding peptic ulcer.

EDWARD W. GIERH, M.D.

Rocadero, P., Mosto, D., and Landabero, J.
Whipple's Intestinal Lipodystrophy (*Lipodistrofia intestinal de Whipple*). *Arch. Soc. Arg.*
1945, 7, 39.

Whipple described the first case of intestinal lipodystrophy in a man of 36 in 1907. In all, 15 cases have been published up to this time, a detailed history of the last one being given in this article. A table is given showing the outstanding features of each case, and the cell findings in the skin and spleen are described in detail and illustrated with photomicrographs.

The case described here was in a man of 27 years who had a history of generalized polyarthritides since he was 19 years of age. The most important digestive symptoms were distention of the abdomen, a feeling of heaviness after meals, and fatty stools. He also had fever, anasthenia, and loss of weight. There was moderate anemia, low blood pressure, and absence of hydrochloric acid in the stomach contents. Histological examination showed increased intestinal villi containing fatty cells, lipomatosis of the glass of the mediastinum and peritoneum, and an increase of the adipose cells in the lungs. There wasocrine atrophy of the pancreas with persistence of the islands of Langerhans which were small and contained few alpha cells. There was atrophy of the epidermis and edema of the dermis. The subcutaneous fatty tissue was atrophied. The fats which remained were more sudanophil than normal and had reverted to the embryonic type. There were foci of embolic glomerulonephritis. There were intense scleroid colloid cysts of the hypophysis. There were ossification, septic foci, and Gandy-Campana nodules in the spleen. These are nodules containing iron from the breaking down of the red blood cells. All cases have ended in death.

The various theories as to the causation of this condition are discussed without arriving at any definite conclusion. The disturbance of fat metabolism is probably an increased excretion, possibly due to lack of vitamin A, which has been shown to be insufficient but it remains to be shown whether the changes are primary or secondary to the disease. The authors are inclined to believe that they are primary.

AURELIO G. MORENO, M.D.

Roettig, L. C., Glesner, B. F. and Barney, C. O.
Definitive Surgery of the Large Intestine following War Wounds. *Ann. Surg.* 1945, 121, 775.

The material upon which the authors study is based consists of 96 consecutive cases admitted to the Septic Surgery Section, Rhoads General Hospital, Utica, New York. The patients were soldiers who had been wounded in overseas theaters of operation, in whom some type of reparative surgery was necessary after overseas definitive surgery of the large intestine. One of the important problems in the management of these cases was that of determining the optimum time to institute reparative surgery. The solution varied with each individual case and depended greatly upon the number extent and

agency of the procedures contemplated. As a rule, major surgery was withheld until all clinical and laboratory evidence of malnutrition had disappeared. Whenever possible the patient was carefully managed until he had regained all but 10 pounds of his former body weight. Many of the patients had multiple wounds of varying severity.

The most important problem of reparative surgery of the large bowel was closure of the colostomy. In the present series, 86 colostomies were repaired. In 6 instances it was necessary to construct a second colostomy proximal to a former colostomy or to a traumatic colostomy in which it was desirable to completely divert the fecal stream for defunctional indications for secondary colostomy. When definite opinion of the authors that it should be performed unhesitatingly on the basis of obviating additional surgery and added morbidity and of improving the end results.

A total of 14 persistent fecal fistulas were encountered 7 of which were the result of unsuccessful attempts at closure of the colostomy overseas by the extraperitoneal method. The others were the result of surgical and traumatic cecostomies, traumatic colostomies, and rectal perforations. It is desirable to perform a cecostomy preparatory to the repair of a fecal fistula in the transverse or descending colon.

Penetrating wounds of the rectum which had been produced by a missile perforating the sacrum or the sacrum and coccyx were present in 9 patients in 2 of whom healing occurred spontaneously following a proximal colostomy which completely diverted the fecal stream. Perforated capsules of sulfaguanidine (1 gm. three times a day) were inserted into the distal loop. The distal loop was irrigated with a 1 to 10,000 solution of acriflavine using 500 c.c. three times a day. Externally, wet dressings of penicillin were applied. However in 7 patients the colostomy did not close spontaneously under this management. Most of these patients developed an osteomyelitis of the sacrum or coccyx. Closure of the fistula occurred only after removal of the infected bone. There was a marked tendency to eversion and proliferation of the rectal mucosa in front of the sacrum and along the anus tract. The authors state that 3 important steps are required for successful surgical closure of the coccyx and of as much of the sacrum as is safely permissible and necessary to allow adequate exposure. Secondly it is important to achieve as much mobilization of the rectum as possible both laterally and in front of the sacrum. Finally it is important to interpose some fat or muscle tissue between the portion of rectum containing the transverse closure and the sacrum before closing the transverse wound is then closed tightly without drainage. The cardinal points in the management of rectovaginal fistulas are a completely defunctioning proximal colostomy and a satisfactory suprapubic cystostomy in conjunction with an indwelling urethral catheter. If these two operative procedures

were carried out promptly and satisfactorily the communication between the rectum and bladder usually healed spontaneously, as did the communication between the bladder and abdominal wall.

For the most part retained abdominal or pelvic foreign bodies found in conjunction with large bowel wounds were asymptomatic. No attempt was made to remove these. Removal became necessary only when they were responsible for persistent sinus leading to the colon or perineal, colonic or rectal abscess or phlegmon.

Extensive laceration of the anal sphincter was encountered in 7 cases. The repair of these required multiple operations. Despite extensive loss of sphincter substance, it was possible to restore satisfactory function in all cases after a defunctioning colostomy had diverted the fecal stream. After plastic repair several weeks of dilatation and sphincter control exercises were instituted then a second operation was performed in which the severed ends of the sphincter were united. When more than one interruption of the sphincter was present one transection was repaired at a time. Daily sphincter control exercises and daily dilatation are believed to be very important in the management of these cases.

Preoperative preparation with sulfaguanidine was an important factor in the success of colostomy closure. The distal loop was irrigated three times daily and sulfaguanidine was inserted into the distal loop in perforated capsules. Vitamin K was administered.

Closure of colostomy for the most part was performed as an intraperitoneal procedure similar to an end-to-end anastomosis.

The most significant postoperative feature according to the authors was oral starvation except for small amounts of liquids and sulfadiazine. The daily caloric, fluid, and vitamin requirements were met by intravenous therapy and parenteral amino acids were given to provide 30 grams of protein daily. By the second postoperative day practically all patients passed flatus per rectum. Beginning on the fifth or sixth postoperative day the oral intake was gradually increased until a full diet was reached by the twenty fourth postoperative day. In all a total of 108 large bowel operations were performed with no fatalities. Three patients developed fecal fistulas and of these only 1 patient required surgical correction. Nine patients showed wound infection while 4 patients developed a ventral hernia at the site of closure.

The eminently successful results with intraperitoneal closure obtained by the authors recommends it as a procedure to be followed in civilian surgery.

Morton, J. J. Jr.: Diverticulitis of the Colon. *Ann. Surg.* 1946, 124, 725.

The author's classification of diverticulitis is as follows:

1. Diverticulosis
2. Diverticulitis with spasm.

HAROLD LAURMAN, M.D.

If the presence of peptic ulcer is established the advisability of early surgery must be considered. If bleeding is moderate and appears to cease promptly the patient should be managed by nonoperative measures.

If the bleeding is massive, continuous, or recurrent, and particularly if the patient is past 60 years of age, operation should be performed after adequate blood replacement therapy. The progress of bleeding may be estimated by clinical examination and by frequent blood pressure, red cell, hemoglobin, and hematocrit determinations. Digestion of blood in the gastrointestinal tract produces an elevation of the blood urea nitrogen and affords an excellent guide to the amount of blood loss and to the continuance or recurrence of hemorrhage.

The author's plan for the management of patients with bleeding peptic ulcer is described in detail. Usually these patients may be placed in one of the following groups:

1. Patients with known chronic peptic ulcer who bleed seriously while under treatment. These should be operated upon promptly.

2. Patients with duodenal ulcer who have been operated upon previously. These will usually bleed from a gastrojejunal ulcer and will usually respond to nonoperative treatment. If bleeding persists operation may become necessary and may be quite complicated and difficult.

3. Patients in whom the source of bleeding cannot be definitely established. These will require thorough study and much caution in the selection of therapy.

4. Patients with perforation, obstruction, or other complications in addition to hemorrhage. These require prompt operation.

5. Patients in any of the groups given who suffer repeated severe hemorrhages. These may require surgical treatment unless one can definitely establish that the bleeding is due to some condition other than ulcer.

The type of operative procedure must be selected for each case. The patient is brought to the operating room while receiving a transfusion. A tube is placed in the stomach and anesthesia is induced by intratracheal administration of cyclopropane and oxygen with or without ether. A transverse upper abdominal incision is preferred. Excision of the ulcer with partial gastrectomy is the method of choice, but the condition of the patient may not permit a procedure of this magnitude. Ligation of the vessels from outside the stomach may control bleeding from a gastric ulcer, but a duodenal ulcer will require duodenotomy with transfixion suture of the ulcer bed around the bleeding site, followed by closure of the duodenum or by resection. Bleeding from a diverticulum or neoplasm usually requires resection of the offending lesion.

Four brief case reports illustrate some of the more difficult problems encountered in the management of these patients with bleeding peptic ulcer.

Escudero, P., Mosto, D., and Landis, J.
Whipple's Intestinal Lipodystrophy (Lipodystrophia Intestinal de Whipple) *Arch. Soc. esp. med.* 1945 7:159.

Whipple described the first case of intestinal lipodystrophy in a man of 36 in 1907. In all, 15 cases have been published up to this time, a detailed history of the last one being given in this article. A table is given showing the outstanding features of each case, and the cell findings in the skin and organs are described in detail and illustrated with photomicrographs.

The case described here was in a man of 37 years who had a history of generalized polyarthritides since he was 19 years of age. The most important subjective symptoms were distention of the abdomen, a feeling of heaviness after meals, and fatty stools. He also had fever, anorexia, and loss of weight. There was moderate anemia, low blood pressure, and absence of hydrochloric acid in the stomach contents. Histological examination showed increased intestinal villi containing fatty cells, lipomatosis of the pleura of the mediastinum and peritoneum, and an increase of the adipose cells in the lungs. There wasocrine atrophy of the pancreas with persistence of the islands of Langerhans which were small and contained few alpha cells. There was atrophy of the epidermis and edema of the dermis. The subcutaneous fatty tissue was atrophied. The fats which normally were more sudanophil than normal and had reverted to the embryonic type. There were foci of eosinophilic glomerulonephritis. There were intense sclerous and colloid cysts of the hypophysis. There were congestion, septic foci, and Gandy-Gamma nodules in the spleen. These are nodules containing iron from the breaking down of the red blood cells. All cases here ended in death.

The various theories as to the causation of this condition are discussed without arriving at any definite conclusion. The disturbance of fat metabolism is probably an increased excretion, possibly due to lack of vitamin A, which has been shown to be insufficient, but it remains to be shown whether the changes are primary or secondary to the arthritis. The authors are inclined to believe that they are primary.

AUGUST G. MORGAN, M.D.

Roettig, L. C., Glaser, B. F., and Barney, C. O.
Definitive Surgery of the Large Intestine Following War Wounds. *Ann. Surg.* 1946, 124: 135.

The material upon which the authors study is based consists of 96 consecutive cases admitted to the Septic Surgery Section, Rhoads General Hospital, Utica, New York. The patients were soldiers who had been wounded in overseas theaters of operation, in whom some type of reparative surgery was necessary after overseas definitive surgery of the large intestine. One of the important problems in the management of these cases was that of determining the optimum time to institute reparative surgery. The solution varied with each individual case and depended greatly upon the number, extent, and

gency of the procedures contemplated. As a rule, major surgery was withheld until all clinical and laboratory evidence of malnutrition had disappeared. Whenever possible the patient was carefully managed until he had regained all but 10 pounds of his former body weight. Many of the patients had multiple wounds of varying severity.

The most important problem of reparative surgery of the large bowel was closure of the colostomy. In the present series, 86 colostomies were repaired. In 6 instances it was necessary to construct a second colostomy proximal to a former colostomy or to a traumatic colostomy in which it was desirable to completely divert the fecal stream for defunctionation of this portion of the colon. When definite indications for secondary colostomy are present it is the opinion of the authors that it should be performed unhesitatingly on the basis of obviating additional surgery and added morbidity and of improving the end results.

A total of 14 persistent fecal fistulas were encountered 7 of which were the result of unsuccessful attempts at closure of the colostomy overseas by the extraperitoneal method. The others were the result of surgical and traumatic cecostomies, traumatic colostomies, and rectal perforations. It is desirable to perform a cecostomy preparatory to the repair of a fecal fistula in the transverse or descending colon.

Penetrating wounds of the rectum which had been produced by a missile perforating the sacrum or the sacrum and coccyx, were present in 9 patients. In 2 of whom healing occurred spontaneously following a proximal colostomy which completely diverted the fecal stream. Perforated capsules of sulfaguanidine (1 gm. three times a day) were inserted into the distal loop. The distal loop was irrigated with a 1 to 10,000 solution of acriflavine, using 500 c.c. three times a day. Externally, wet dressings of penicillin were applied. However in 7 patients the colostomy did not close spontaneously under this management. Most of these patients developed an osteomyelitis of the sacrum or coccyx. Closure of the fistula occurred only after removal of the infected bone. There was a marked tendency to eversion and proliferation of the rectal mucosa in front of the sacrum and along the anus tract. The authors state that 3 important steps are required for successful surgical closure of trans-sacral rectal defects. The first step is excision of the coccyx and of as much of the sacrum as is safely permissible and necessary to allow adequate exposure. Secondly it is important to achieve as much mobilization of the rectum as possible, both laterally and in front of the sacrum. Finally it is important to interpose some fat or muscle tissue between the portion of rectum containing the transverse closure and the sacrum before closing the skin. The wound is then closed tightly without drainage.

The cardinal points in the management of recto-ovococcygeous fistulas were a completely defunctioning proximal colostomy and a satisfactory suprapubic cystostomy in conjunction with an indwelling urethral catheter. If these two operative procedures

were carried out promptly and satisfactorily the communication between the rectum and bladder usually healed spontaneously, as did the communication between the bladder and abdominal wall.

For the most part retained abdominal or pelvic foreign bodies found in conjunction with large bowel wounds were asymptomatic. No attempt was made to remove these. Removal became necessary only when they were responsible for persistent sinus leading to the colon or pericecal colonic or rectal abscess or phlegmon.

Extensive laceration of the anal sphincter was encountered in 7 cases. The repair of these required multiple operations. Despite extensive loss of sphincter substance, it was possible to restore satisfactory function in all cases after a defunctioning colostomy had diverted the fecal stream. After plastic repair, several weeks of dilatation and sphincter control exercises were instituted then a second operation was performed in which the severed ends of the sphincter were united. When more than one interruption of the sphincter was present one transection was repaired at a time. Daily sphincter control exercises and daily dilatation are believed to be very important in the management of these cases.

Preoperative preparation with sulfaguanidine was an important factor in the success of colostomy closure. The distal loop was irrigated three times daily, and sulfaguanidine was inserted into the distal loop in perforated capsules. Vitamin K was administered.

Closure of colostomy for the most part was performed as an intraperitoneal procedure similar to an end-to-end anastomosis.

The most significant postoperative feature, according to the authors was oral starvation except for small amounts of liquids and sulfadiazine. The daily caloric fluid and vitamin requirements were met by intravenous therapy and parenteral amino acids were given to provide 30 grams of protein daily. By the second postoperative day practically all patients passed flatus per rectum. Beginning on the fifth or sixth postoperative day the oral intake was gradually increased until a full diet was reached by the twenty fourth postoperative day. In all, a total of 108 large bowel operations were performed with no fatalities. Three patients developed fecal fistulas, and of these only 1 patient required surgical correction. Nine patients showed wound infection, while 4 patients developed a ventral hernia at the site of closure.

The eminently successful results with intraperitoneal closure obtained by the authors recommends it as a procedure to be followed in civilian surgery.

HAROLD LAUFMAN, M.D.

Morton, J. J., Jr.: Diverticulitis of the Colon. *Ann. Surg.* 1946 124 725

The author's classification of diverticulitis is as follows:

- 1 Diverticulosis
- 2 Diverticulitis with spasm.

3 Diverticulitis with complications (a) perforation (b) sinus and fistula (c) obstruction (d) complicating or masking other disease

Diverticulitis with spasms rarely occurs in patients under 40 years of age. The typical history reveals a middle-aged or older corpulent individual who has been habitually sedentary and constipated and who is suddenly seized with cramplike pain in the lower abdomen accompanied by increasing constipation. The condition is often ushered in by the passage of several loose stools. Signs of inflammation follow according to the degree of involvement.

Of 111 patients, 91 had pain as a predominant symptom, usually in the lower abdomen and on the left side. Constipation was present in 45 patients; diarrhea in 37; distention in 31; fever in 19; and vomiting in 18 patients. Blood in the stools was present in 24 patients. Diverticulitis with spasms is a self-limited disease according to the author and should subside or improve in a period of from 3 or 4 days to a week under good medical care.

In 39 patients with diverticulitis there was perforation. In 3 there was perforation into the free peritoneal cavity with extensive peritonitis; 2 of these patients recovered. Of 36 patients with localized abscess subjected to drainage, 24 recovered and 12 died in the hospital. Of the 36 patients with localized abscess, 18 had fistula formation or obstructions. These patients were very ill from the start and improved appreciably with rest and therapy. Barium showed extravasation of fluid outside the bowel lumen on three occasions and free air in the peritoneal cavity was twice observed. In 3 instances the abscess had perforated into the extraperitoneal rectal space and extended into the soft tissues so that it simulated an extravasation of urine with swelling and crepitation under the skin in the region of the scrotum and penis.

Twenty-two patients had known fistulas. In 11 openings were present from the sigmoid to the skin in 8; from the sigmoid to the urinary bladder in 2; from the sigmoid to the urethra in 2; from the sigmoid to the small intestine in 1; patient from the sigmoid to the cecum in 1; from the sigmoid to the rectum in 4; patients from the sigmoid to the vagina in 1; there was a sinus to the retroperitoneal tissues in 1; an ischio-rectal sinus and in 1 a sinus into the mesocolon. Most of the complaints of these patients were of leaking fistulous openings, or of symptoms referable to the organ involved, but there were no signs of severe infection.

Obstruction to the bowel was found in 34 patients. In 18 of these there was partial obstruction at the sigmoid area while in 13 there was complete obstruction in the same region. Obstruction may result from scarring and thickening or from adhesions. In 3 patients there was obstruction of the small intestine adherent to the inflammatory mass.

Often, the diagnosis of diverticulitis from carcinoma is practically impossible. Even when the surgeon has the lesion in his hand, he cannot be sure whether it is a chronic inflammation or a neoplasm.

In women, diagnostic difficulties often confront the gynecologist; the left tube and ovary frequently become attached to the inflamed sigmoid, and a diagnosis of solid tumor of the ovary may be made. Such errors can be obviated by careful studies with barium enema. Another pitfall for the gynecologist is the fecal fistula resulting after drainage of a pelvic abscess. Extravasation of urine has been considered in some cases as a differential diagnosis. Frequently associated infection of the prostatic tract is noted. Pyelitis, pyelonephritis, or cystitis may clear up after diverticulitis has been eliminated. The roentgenologist also is often times misled by the differential diagnosis between diverticulitis with obstruction and cancer. Aids in roentgen diagnosis are such features as nodulation of the lesion, tenderness of the bowel, and distensibility.

The author offers no new suggestions for treatment but advocates the Devine colostomy in the right transverse colon for the purpose of defining the colon in the treatment of fistulas to the skin or bladder.

HAROLD LACROIX, M.D.

Care, II. W.: Late Results in the Treatment of Ulcerative Colitis. *Ann. Surg.* 1948, 127:72

This article deals mainly with the evaluation of late results as a guide to the advisability of continuing radical surgery in the treatment of ulcerative colitis. Of a total of 101 patients operated upon, 9 of the 80 surviving patients were personally interviewed by the author. The length of time which had elapsed since operation varied from 10 years to 1 year.

In the author's opinion, the fact that 95 per cent of those individuals who underwent radical surgical management have gained considerable weight, are relieved of annoying, bloody diarrhea, and are afebrile is significant and encouraging. The average weight gain for these 50 patients is 45 pounds. Some patients gained as much as 120 pounds following the removal of their colons. One patient gained only 16 pounds. In 2 patients it was possible to take down the ileostomy successfully and restore the fecal stream by ileosigmoidostomy.

Ileostomy revision for prolapse had to be carried out to relieve obstruction or to prevent gangrene of the protruding intestine in 11 patients. Of these 5 came to revision on account of obstruction. Aside from prolapse of the ileostomy the greatest problem in these patients is that of the prevention of irritation of the skin around the ileal stoma. The author believes that the best and most satisfactory treatment of the skin is the application of a dry dusting powder of Fuller's earth (kaolin). The skin should be bathed once or twice daily with soap and warm water and the powder or kaolin freely applied.

Acute or intermittent ileus due to adhesions or volvulus at or near the ileostomy opening brought 4 patients to surgery. A volvulus about the ileum was present in 1 and in 1 patient the ileostomy had to be moved from the right to the left lower quadrant due to two episodes of obstruction from volvulus.

There were striking instances of repeated collapse from sudden salt deprivation due to unexplainable abrupt and profuse diarrhea through the ileal stoma in 3 patients. Once such an attack has occurred patients learn to recognize the prodromal symptoms and can avert an attack with salt tablets or intravenous saline. All patients are encouraged to use an abundant amount of salt in their food in order to maintain a high sodium chloride blood level.

Primary ileosigmoidostomy leaving the colon intact, was performed in 11 cases. One of these patients progressed satisfactorily for a period of 5 years, until she began to have a series of severe symptoms, including diarrhea with blood pus and mucus, and rapid loss of weight. Roentgenograms revealed ulceration of the distal 18 inches of ileum and resection had to be performed.

In 4 of the younger female patients pregnancy occurred and therapeutic abortions were carried out for fear of disturbance in the ileal stoma.

Practically all patients who have been colectomized after ileostomy but who have retained their rectal pouch have a fair amount of discharge through the anal opening two or three times a day. When the discharge is annoying and malodorous, a rectal lavage biweekly has proved helpful.

Careful interrogation into the diet habits of these patients in an attempt to arrive at a standard diet led to no agreement among the patients. Many of them eat practically everything while some avoid certain specific foods which they claim do not agree with them. Of the 50 patients 40 are at work ranging from manual labor to white collar jobs. Many of the younger patients are able to play golf, baseball and tennis. A few even swim in the ocean.

In the group of 101 patients there were 3 who showed malignant changes originating in a polyp in some part of the colon. These 3 patients are still alive—one, 7 years, one 5 years and the other 3 years after colectomy.

Frequently following the removal of the rectum as the third and final stage in the surgical treatment of this disease the ileostomy takes on in some degree the functions of the rectum. The ileal contents become more solid the lumen appears to enlarge and the walls thicken. HAROLD LAUFMAN, M.D.

Ehrenpreis, T: Megacolon in the Newborn. *Acta chir scand.* 1946 94 Supp 112

Since Hirschsprung's demonstration in 1886 of the disease with which his name is synonymous, congenital megacolon has been considered by many investigators, none of whom have satisfactorily elucidated the primary etiology of the condition. Three distinct trends as to the pathogenicity of megacolon have been held: (1) the malformation theory (of Hirschsprung) assumes a congenital anatomical dilatation and hypertrophy of the colon to be present; (2) the obstruction theory contends that the dilatation arises from mechanical obstruction to passage as the result of an abnormally redundant sigmoid which predisposes to valve action kinks or volvulus

and (3) the neurogenic theory which indicts an overly active sympathetic nervous system (or decreased parasympathetic activity) as the causal factor. This last has been held tenable owing to the beneficial results obtained from sympathectomy although experimental evidence is inconclusive.

Working at the Kronprinsessan Lovisas Children's Hospital in Stockholm the author has intensively studied 10 cases of disease of the megacolon beginning at birth. The infants were subjected during the first 10 days to clinical and x-ray examination and were subsequently followed. One hundred normal infants were similarly examined for purposes of comparison. The studies revealed fairly uniform clinical courses and roentgenograms showed the condition to be of early development. Symptoms of obstipation, abdominal distention and vomiting appeared within 7 days after birth. Scout films and contrast enemas showed gaseous distention of the bowel, a marked retention of the enema and almost no contractile activity of the large bowel in comparison to the normal. The size of the colon was seen to be within normal limits although slightly larger than the average for normal infants. Redundancy of the sigmoid was no greater than in the normal newborn infant in whom such a state was found to be a normal constant physiological phenomenon. No mechanical obstruction was present in any of the cases. Over a period varying from 18 days to 3½ months there was a transition from essentially normal bowel measurements to the typical megacolon picture. A deficiency in the contractile and evacuation power of the colon was evident from the onset.

Megacolon in the beginning consists primarily of an ileuslike state which is identical in appearance to simple meconium retention or to bowel obstruction resulting from atresia or stenosis. From the latter it may be distinguished by contrast enema and from the former by the clinical course in that meconium retention is relieved by evacuation of the bowel whereas the obstipation of megacolon persists over a period of weeks to months until the typical picture of dilatation of the colon with a froglike belly is developed.

The author concludes that the theories regarding malformation and obstruction of megacolon are highly questionable. A sympathetic hyperfunction appears to be involved in the cause of megacolon but the nature of the disturbance has not been determined. He therefore defines megacolon disease as a dysfunction of the evacuation of the colon of an as yet unknown origin occurring in the absence of morphological or mechanical causations and giving rise secondarily to a characteristic dilatation of the colon. WAYNE CAMERON, M.D.

Casco, G. M.: A New Technique for Temporary Cecostomy (Nueva técnica para el uso cecal temporario). *Rev. As. med. argent.* 1946 60 3.

The author describes a technique for a hermetic cecostomy whereby the taenia of the cecum is infiltrated with some inert fluid such as water or pro-

Fig. (Casco)

came in order to form a suitable bleb 6 by 4 cm. The dome of the bleb is then incised and the resultant flaps are sutured to the aponeurosis of the external oblique muscle after iodine is applied to the peritoneal opening and the flaps.

The iodine produces a thick fibrin effusion which insures attachment and seal against subsequent leakage (Fig. 1). The protruding muscularis portion is now pulled upward and a pursestring suture which anchors a Paul tube *in situ* is applied.

The same technique is applicable to colostomies which may be made by utilization of the transverse colon.

STEPHEN A. ZIEGLER, M.D.

Joffe H. H., and W. Hs. A. H.: Normal Appendices in 1,000 Appendectomies. *Minnesota M.* 946 29 1019.

In a review of 1,000 consecutive appendectomies performed by 37 surgeons it was noted that 275 of the appendices removed showed no pathological condition or only obliteration of the lumen without any active inflammatory process.

A study of this group of case records disclosed that a small group of surgeons was responsible for a relatively high percentage of the diagnostic errors. In spite of the pathologist's report of normal appendix, the final clinical diagnosis of the case records was seldom found to be corrected from the original working diagnosis.

The records of the clinical manifestations were quite inadequate for an intelligent summarization,

but it was apparent that obvious signs of disease outside of the appendix were often disregarded.

The authors estimate that normal appendices should constitute not more than from 15 to 20 per cent of the appendices removed where good surgical practice is carried out.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Brunschwig, A., and Morton, D. R.: Resection of Abdominal Carcinomas Involving the Liver and Spleen Secondarily. *Ann. Surg.* 1946, 124 246.

The purpose of this communication is to summarize the experiences gained in a limited series of patients who at celiotomy presented carcinoma primary in an abdominal viscus with direct spread to the liver or with metastases in the liver or spleen, and in whom the primary growths were excised en masse with the spread into the liver; or those in whom the primary growths were excised as well as hepatic or splenic metastases at the same sitting.

In 10 patients with primary malignant neoplasms in various abdominal viscera and with direct spread of one or a few metastases into the liver or spleen the primary growths were excised en masse with the direct extensions in the liver or with resection of the discrete metastases that were visible. The immediate surgical mortality was 10 per cent (1 patient).

The best results were observed when the neoplasms had spread to the liver and discrete metastases were not present. It is suggested that increased palliation might have been achieved in some instances in which metastases were excised, but sufficient time has not elapsed for more definite evaluation of this impression.

Savagnone L. and Citarda, A.: Clinical Contribution to the Study of the Relationship between Biliary Stasis and Hepatic Lesions. (Contributo clinico allo studio dei rapporti fra stasi biliare e lesioni epatiche). *Pediatrics* 1946, 44, 53-4.

Two cases are presented in which different etiological factors contributed to a similar clinical picture of severe hepatic insufficiency on a basis of biliary stasis. In the first case a chronic inflammation of the pancreas with subsequent appearance of an adenoma in the cephalic portion gave rise to abundant adhesions around the duodenum, gall bladder and bile ducts and the development of a painless, intense jaundice, a variable low grade hypopyrexia, and the laboratory findings of an obstructive jaundice. In the second case a primary carcinoma of the gall bladder had given rise to metastases to the liver and lungs. In both cases signs of hepatic insufficiency had been superimposed upon those of an extrahepatic obstructive lesion, and ascites formation had led to death in from 6 to 12 months. Autopsy showed a profound disturbance of the lobular architecture and extensive proliferation of connective tissue elements in the first case. In the second case there

was evidence of interstitial hepatitis combined with metastatic nodules.

These cases are offered as evidence that obstruction and biliary stasis even on different bases can produce a similar clinical picture.

EDITH B. FARNSWORTH, M.D.

Mahoney E. B. Cholecystoduodenocolic Membranes. *Surgery* 1946 20 704.

One of the most common anatomic peritoneal variations is the cholecystoduodenocolic fold which is essentially an extension of the normal hepatoduodenal ligament to include the gall bladder. Second portion of the duodenum and the hepatic flexure of the colon. Mahoney attempted to evaluate the clinical importance of this congenital peritoneal anomaly which occurs in 18 per cent or more of patients but causes symptoms in a very few individuals.

In the past there has been considerable controversy about the etiology of these peritoneal bands. Some investigators thought them to be the result of localized peritonitis which may have started in fetal life while other observers believed that they were the result of excessive abnormal development of normal peritoneal folds. Harvey in 1918 after an exhaustive study concluded that these membranes often developed in fetal life as a result of abnormal growth and that the congenital type could definitely be differentiated from that resulting from inflammatory processes in the upper abdomen.

The congenital peritoneal attachments are most frequently seen about the gall bladder. At the Strong Memorial and Rochester Municipal Hospitals (Rochester, New York) only 18 cases have been found in which the upper abdominal symptoms have been considered to be due to congenital attachments.

Fig. 1 (Mahoney) Appearance of cholecystoduodenocolic membrane on opening the abdomen

Fig. 2 (Mahoney) Cholecystoduodenocolic membrane after partial mobilization.

Harris, in 1914, was the first observer in this country to call attention to the role of congenital bands in producing abdominal symptoms. All patients had disturbance of digestion characterized by epigastric distress 2 to 3 hours after eating which was usually followed by nausea and emesis with subsequent relief of pain. Tenderness in the epigastrium was present and the gastric analysis showed hyperchlorhydria only 1 of Mahoney's 18 cases had hyperchlorhydria. Homans in 1916 first emphasized the similarity of symptoms caused by these congenital bands to gall bladder disease and/or duodenal ulcer. Taylor and Kantor have described a typical roentgenographic deformity which consists of a high fixation of the duodenum associated with a dilated ptotic stomach and a sharp angulation between the first and second portions of the duodenum; this was not observed consistently in Mahoney's cases.

Of Mahoney's 18 patients 6 had symptoms suggestive of cholecystic disease, 7 had ulcerlike symptoms which also suggested partial duodenal obstruction and 5 had vague upper abdominal symptoms that could be classified neither as ulcerlike or gall bladderlike. A correct preoperative diagnosis of congenital bands was made in 5 cases; in the remainder a diagnosis of chronic cholecystitis was made in 8 cases of duodenal ulcer in 2 and of tumor of the ampulla of Vater, chronic appendicitis and questionable carcinoma of the hepatic flexure of the colon in 1 case each.

The operative procedure employed in this series of 18 cases was cholecystectomy and division of the bands in 8 cases and division of the bands without cholecystectomy in 10 cases. One of the 10 patients also had a Heineke-Mikulicz pyloroplasty because of definite narrowing of the duodenum as a result of the pressure from the band.

The type of congenital bands seen at operation varied considerably. The most commonly encountered type which incidentally is the most extensive type seen is illustrated in Figures 1 and 2. It is attached over the entire gall bladder and spreads out to involve the duodenum, the hepatic flexure and the proximal portion of the transverse colon which may be narrowed by the band.

The operative results were as follows: 13 patients are considered cured, 3 are benefited and 2 are not benefited. Those patients who had severe pain were benefited by the operation. The patients with equivocal symptom had equivocal results. The patients who were not cured had no other demonstrable organic cause of complaint. R. AUST TUNELL, M.D.

Marble, A., and McKittrick, L. S.: Islet Cell Tumor of the Pancreas with Hyperinsulinism. *England J. M.* 1946, 235 637.

Six cases of islet cell tumor of the pancreas with hyperinsulinism were verified at operation are reported. In 5 cases removal of a single adenoma resulted in a relief of symptoms that had persisted from 4 to 7 years before operation. In 1 case death occurred in 7 weeks after operation. This patient was found to have an islet cell carcinoma, with multiple metastases in the liver.

Of the 5 patients with benign adenoma, 3 were females and 2 were males. The ages of the patients at the time of operation ranged from 16 to 49 years and the patients were seen in from 3 to 8 years after the onset of symptoms. In 4 cases the tumor occurred in the head of the pancreas and in 1 in the body of the pancreas. Two of these patients had been operated on previously without the discovery of a tumor.

The patient with carcinoma was a woman 59 years of age at the time of operation with symptoms of 4 years duration. In this case the primary tumor was in the tail of the pancreas.

Microscopic examination of tumor tissue from the 5 patients with adenoma showed the capsule of the tumor to be incomplete in each of 4 cases in which there was enough tissue available for satisfactory examination. In 1 case questionable blood vessel invasion was noted.

In the 4 cases in which assays were carried out the insulin content ranged from 3 to over 100 units per gram of tumor tissue.

The important features in the diagnosis of islet cell tumor are the characteristic symptoms associated with well marked hypoglycemia (blood sugar concentrations usually below 50 mgm. per 100 c.c.) brought on by fasting increased by physical exertion and relieved by food. The glucose tolerance

test is of aid in diagnosis only if it is carried out in a sufficient length of time—4 to 6 hours—to allow the blood sugar to fall to an abnormally low level.

Because of the danger of damage to the central nervous system by repeated attacks of prolonged hypoglycemia, and because of the possibility of malignant degeneration of a tumor initially benign, early exploratory operation is urged in patients in whom the diagnosis of islet cell tumor with hyperinsulinism has been made. CLEVELAND BAKER, M.D.

MISCELLANEOUS

Altmeier W. A.: The Treatment of Penetrating Wounds of the Abdomen in Civilian Practice. *Surg. Clin. N. America*, 1946, 26 1152.

The author reports a series of 161 cases of penetrating wounds of the abdomen treated in the Cincinnati General Hospital, Cincinnati, Ohio, from 1942 to 1946. The over-all mortality rate in this series was 74.5 per cent.

Preoperative preparation consisted of the use of morphine, oxygen, shock position, and the intravenous injection of fluids. He believes that whole blood is far superior to plasma or any other solution in the treatment of shock associated with penetrating wounds of the abdomen. If necessary 2 and even 3 transfusions were carried out at once, at least 1 of which was in an arm vein if bleeding from the venous cava was feared. The systematic administration of 3 gm. of sodium sulfadiazine preoperatively by intravenous injection was routinely carried out.

The operation was performed under a general anesthetic as soon as the general condition of the patient would permit. The arrest of hemorrhage was the first objective. The author stresses the necessity of early suturing of all perforations of the diaphragm in order to minimize pleural contamination and the resultant severe pleural infection. The danger of overlooking tangential wounds at the junction of the mesentery and the small bowel, as well as wounds of the retroperitoneal portions of the colon and duodenum, is emphasized. If resection was necessary an aseptic end-to-end anastomosis was performed. Large bowel lesions were treated similarly; externalization procedures were not carried out. A proximal colostomy was always established in wounds of the rectum. No drainage of the peritoneal cavity was carried out but the retroperitoneal tissues, if involved were always drained. Sulfanilamide was not used locally in the peritoneal cavity; the drug was given parenterally both before and after operation. Penicillin was sometimes used in connection with the sulfa drug. The wounds were closed with through-and-through silver or wire sutures.

The causes of death were hemorrhage in 7 cases, pneumonia in 4 cases, empyema in 4 cases, and peritonitis in only 2 cases (8 per cent of the deaths). By contrast in a series of 104 cases compiled before the advent of chemotherapy peritonitis was the cause of death in 9 cases (31 per cent of the deaths).

J. J. LEEBMAN, JR., M.D.

Bogle J. H.: War Wounds of the Abdomen. A Review of 131 Cases. *Am. J. Surg.* 1946 72 656.

Of the 131 patients with gunshot wounds of the abdomen upon whom Bogle operated 28 died a mortality rate of 21.3 per cent.

Preoperative care consisted in careful inspection of the patient making him dry and warm noting the emergency medical tag for what previous treatment had been ordered appraisal of the patient's wounds, catheterization to rule out injury to the urinary tract and checking of the patient's blood pressure and pulse in order to determine the imminence of shock. Shock treatment was undertaken by a shock team which administered whole blood in amounts up to 5,000 and 6,000 c.c. At the same time, sulfadiazine and penicillin therapy was begun. A Levine tube was inserted into the stomach and Wangenstein suction applied.

As soon as the patient's condition warranted it, anteroposterior and lateral x-rays were taken. In all abdominal wounds, films were taken of the chest as well as of the abdomen and vice versa. The position of the missile or missiles was located and this knowledge in combination with the position of the wounds, gave the surgeon a fairly accurate idea of the path the missile had taken and the organs that were probably injured. It also frequently settled the question of whether or not a thoracoabdominal wound was present.

In the operative treatment gas-oxygen-ether was used in all abdominal cases and was given by the closed system. In cases in which the chest was also involved intratracheal anesthesia was always used and it was also used in many of the purely abdominal cases as well.

Wounds of the back were usually debrided first so that the patient would not have to be turned for this purpose at the end of a long operation. By the same token if the patient was in poor condition after an abdominal operation and it was judged he would not stand further procedures on other multiple injuries such as compound fractures of the extremities, these were put in traction or plaster splints and debrided at a later date.

If a thoracoabdominal wound was present and thoracotomy was necessary this was usually done first and the laparotomy second if the necessary procedures could not be done through the thoracotomy incision.

The type of incision used was based on the position of the wounds and the findings of the roentgen examination.

After sucking and mopping out of the peritoneal cavity, active bleeding was looked for. Then the small intestine was inspected in its entirety and all perforations tagged with clamps. The small intestine was then eviscerated while the other organs within the peritoneal cavity were inspected. This is an important time saving procedure and here again an adequate incision is necessary or the small gut will become markedly congested while it is being held outside.

Injuries of the large bowel may be very deceptive and hard to find and it is absolutely imperative that the operator be sure whether or not there are any perforations in it.

When a penetrating wound of the anterior wall of the stomach is present the gastroduodenal omentum should be incised and the posterior wall inspected. If there is still doubt, an anterior gastrotomy may be done and the missile searched for within the lumen of the stomach.

Injuries of the colon were treated by means of exteriorization in nearly all cases. Small intestinal injuries were repaired if at all possible. If this was not possible resection and usually end-to-end primary anastomosis were done.

Injuries of the intraperitoneal and retroperitoneal portions of the rectum are very serious. The diagnosis may be made by digital examination proctoscopy or deduced from the course of the missile.

Wounds of the liver had usually stopped bleeding when the abdomen was opened. If bleeding was present it might be necessary to pack the liver.

Lacerations of the duodenum are difficult to repair and are usually associated with other grave injuries. The duodenum must be mobilized adequately to get at least a 2 layer closure and preferably a 3 layer one.

Lacerations of the gall bladder were treated by cholecystectomy as there were other injuries to be cared for and this procedure was simpler and quicker.

Extreme conservatism was used in treating wounds of the kidney. Nephrectomy was done only when the kidney was grossly fragmented or there was continued bleeding from the renal vessels. Extraperitoneal drainage to the kidney area was provided through a flank incision.

Bladder wounds were treated by doing a suprapubic cystostomy and suturing the lacerations.

At the close of abdominal operations when there had been intestinal injuries with contamination 5 gm. of sulfanilamide mixed with 100,000 units of penicillin powder were dusted into the peritoneal cavity and the layers of the abdominal wall. No intraperitoneal drainage was used except in the presence of liver, pancreatic, and duodenal injuries.

All entrance and exit wounds were thoroughly debrided and loosely packed.

Infection was certainly not a factor in the postoperative course of the great majority of these patients while under observation in field hospitals.

At the end of the operation the patient was sucked out with an intratracheal catheter if necessary until dry and taken to the postoperative ward. He was not moved from the stretcher. The operative procedure had frequently been long and it was necessary to observe the patient closely in the immediate postoperative period. Oxygen was given frequently usually by nasal catheter. Wangenstein suction was applied. Frequently blood was given. Occasionally a patient would lapse into secondary

shock. Concentrated serum albumin was found to be useful in this emergency, although it was often not available. Patients with chest wounds were put in a sitting-up position when possible.

Parenteral fluids were given a minimum of 3,000 c.c. a day (1,000 c.c. of plasma, 1,000 c.c. of physiological saline solution and 1,000 c.c. of 5 per cent glucose in distilled water) until the patient could take fluids by mouth. Fluids lost by gastric suction were replaced by intravenous saline solution. Whole blood was given when indicated and was very useful for giving a patient a boost several days after the operation.

The time intervals between wound and operation ranged from 2 hours to 4 or 5 days and averaged 9.7 hours.

There were 16 cases in which exploratory laparotomy was performed and in 1 fatal case no visceral lesion was found, a mortality rate of 6.2 per cent. These operations were done in cases in which the presence of a visceral injury could not be ruled out. In some the peritoneum had been penetrated or perforated without injury to a viscus.

The data compiled from this group of cases indicate that the mortality from abdominal wounds in World War II is not greatly influenced by the time lag between injury and operation as has been the case in the past. This is probably due largely to the control of infection by the present methods of chemotherapy. The severity of the injury as represented by the extent and multiplicity of the visceral lesions is the major factor influencing the mortality in this series. The mortality rates here reported are similar to others reported in the recent war and indicate a marked reduction as compared with the mortality rates of previous conflicts.

STEPHEN A. ZISMAN, M.D.

Jones, H. W., Jr., Fator, W. H., and Burbank, C. B.: Five Hundred and Twenty-Four Abdominal Wounds on the Western Front. *Bull. Johns Hopkins Hosp.* 94: 79-83.

Despite increasingly lethal weapons in World Wars I and II, the mortality in abdominal wounds that reached surgical care has dropped. An analysis of this improvement is important.

Three of 4 casualties that reached definitive surgical care manifested shock as evidenced by the systolic blood pressure. Intravenous blood and plasma were the mainstays in combating shock. At Alamein, it is reported that 16 units of blood and 20 units of plasma per 100 casualties were used. By the time of the Western Front, similar cases received 120 units of blood and 230 units of plasma per 100 casualties. An attempt to standardize the ratio of blood to plasma was made but it was found best to determine the amount of blood needed by the estimated loss, as determined by the hemoglobin and blood count.

Immobilization of the shock cases was rigidly practiced. Clothes were cut off and x-rays taken only after revival, and all unnecessary handling was

avoided. To avoid ambulance jostling, definite surgical care was given as far forward as possible; early postoperative evacuation of abdominal wounds was avoided. Oxygen was used but was of little importance. Hot water bottles were helpful only in comfort in the winter months. Surgical procedures were disastrous when long major operations were tried on casualties that were not out of shock, but were successfully completed in many cases in which the blood pressure fell to shock levels (80 mm.) after the administration of the anesthetic but before beginning the operation.

Preoperative preparation included, after recovery from shock, passage of a Levin tube with suction, urinalysis, anteroposterior and lateral x-rays of the abdomen. Adequate morphine was given by the intravenous route in shock cases, and operation delayed if morphine had been given substantially during shock until recovery from shock provided evaluation of the patient's reaction to the morphine.

Operation, although near the front, was done with adequate facilities. The duration of operation averaged 1 1/4 hours in 114 cases because of the extreme severity of the procedures. Rapid and accurate operating was stressed. More than 90 per cent of the patients were anesthetized with all-ortho ether either through an endotracheal tube and the remaining 10 per cent were anesthetized with drop ether or spinal anesthesia.

Seventy-five per cent of the incisions were midline or paramedian, 20 per cent midline, 3 per cent subcostal or transverse and 2 per cent miscellaneous. The routine for intra-abdominal exploration was to proceed immediately to the small bowel of the ileo and spleen were not grossly hemorrhaging, examine the bowel, and examine the area from the ileocecal valve or ligament of Treitz. Perforation was marked with dry gauze and the Allis clamp and then repaired. The stomach, duodenum, liver and spleen were next examined. The large bowel was examined with the small bowel eviscerated, suspected areas of injury being approached last. Finally the bladder and kidneys were examined.

The use of sulfanilamide and penicillin in the abdomen was abandoned later in the campaign. The peritoneum was closed with continuous suture, chromic catgut. Interrupted catgut was used in the fascia and silk in the skin. Army directives required stay sutures. Through and through wire with ligature closure also gave good results. Of the 54 cases operated upon, 479 presented intra-abdominal trauma and 45 negative findings, with 1 death in the latter group.

Small bowel injury was the most common abdominal lesion (23%). Bleeding from the small bowel in its mesentery was the most common cause of intra-abdominal hemorrhage. The standard method of treatment was repair of the lacerations and when resection was necessary open end-to-end anastomosis. Ileostomy was never used. The degree of peritoneal contamination in these cases was the most important single factor in the prognosis.

Large bowel injuries were only slightly less common than those of the small bowel. The standard method of treatment was exteriorization without removal fecal diversion. If it was impossible to exteriorize as in the distal sigmoid repair was accomplished by proximal colostomy. The colostomy was preferable through a separate incision but as in exteriorization of the transverse colon, it could be made through the operative wound. Cecal lesions had twice the mortality of other colon wounds. In the latter cases ileotransverse colostomy with exteriorization of the cecum is preferable.

Retroperitoneal hematoma was the third most common finding at celiotomy. Its chief importance is that the preoperative symptoms and findings are indistinguishable from injury to an abdominal viscous. The source of bleeding in the hematoma should not be explored.

The liver was the third most frequently wounded abdominal viscous. Treatment centers about the arrest of the hemorrhage and drainage to provide for the inevitable leakage of bile from the wounded liver. A dry gauze pack usually accomplished both purposes most effectively.

Stomach wounds were usually repaired with care to explore the posterior surface of the stomach by division of the gastrocolic ligament.

Kidney wounds were relatively minor and transperitoneal nephrectomies were necessary in only 47 kidney wounds. Drainage of the perirenal space was adequate for the remaining cases.

Traumatic eversion was of greatest concern because of loss of tissue but most of the cases were closed with the aid of some ingenuity and healed with surprisingly little real trouble.

Bladder wounds were treated by repair and with suprapubic tube and urethral catheter in 16 cases, and by repair and with urethral catheter alone in 12 cases. The latter did well, while the patients with suprapubic tubes often arrived at the rear echelon in poor condition particularly when a concomitant colostomy existed. It was decided therefore in small bladder wounds away from the neck of the bladder that it is best to close them with a double row of catgut with urethral drainage alone. A Penrose drain in the prevesical space can be used for several days.

Rectal wounds require celiotomy to rule out an intra-abdominal wound and to establish proximal colostomy. The perineal wound must be large enough or be enlarged for adequate drainage. In low rectal wounds the rectum and sphincter may be incised from the injury to the outside. There were 8 deaths in 24 cases, this being the highest mortality of any type of injury in spite of the lowest incidence of complicating visceral lesions.

Spleen injuries occurred in 16 cases. 12 required splenectomy and 4 being minor required no treatment.

Great vessel injuries occurred in 7 cases with a mortality of 86 per cent. 3 deaths occurred on the operating table. Ligation was attempted in each case with the exception of 1 in which an attempted

suture of the vena cava was made on its being mistaken for the portal vein.

Gall bladder wounds were treated by the use of a drainage tube (3 cases), cholecystectomy (3 cases), and closure of the laceration (1 case). Laceration of a common duct was closed around a catheter (1 case). Drains were used in all cases.

Ureteral wounds (3) were managed by cutaneous ureterostomy by anastomosis and by implantation in the bladder with complete success only in the last case.

Pancreas injuries (3) were treated only by drainage.

Postoperative care was confined to essentials but adequate and standardized to a large degree with complete but brief records of the fluid intake and output, penicillin intravenous sulfadiazine gastric suction with frequent check and irrigation during the first 5 hours. The daily fluid given was 2,000 c.c. of isotonic saline solution in glucose, 2,000 c.c. of 5 per cent glucose in water and a unit of plasma.

Shock, uremia, atelectasis with pneumonia, and peritonitis were the four principal causes of death in decreasing incidence in the order named. The 6 hours from wounding to surgery are no longer considered necessarily the golden period for operative treatment but principal stress is placed upon the shock state. Bronchoscopy was important in the prevention and treatment of atelectasis and massive pulmonary collapse. Judgment in using fluid and electrolytes is important if pulmonary and other edema is to be avoided.

FREDERICK C. HORRILL, M.D.

Crosby R. C. and Cooney E. A.: Surgical Treatment of Ascites. *V. England J. M.*, 1946 335 361

The authors present a review of the various surgical methods of treating ascites with a detailed description of a method employing a glass button inserted into the abdominal wall which they have used in 7 cases. The authors have added a top plate to the button as used by previous workers in order to prevent the omentum from becoming impacted in the core of the spool and thus blocking the outflow of ascitic fluid.

One great advantage of this therapeutic device is its ease of application. Patients with hepatic cirrhosis do not tolerate major surgery well. Malnutrition, susceptibility to shock, and tympanitis contribute to the high operative mortality. Wound healing is poor unless vitamin C and a great deal of protein are given. The anesthetic tolerance is low since the damaged liver detoxifies the anesthetic agent poorly yet large amounts of anesthetic are usually required for satisfactory anesthesia in patients with alcoholic liver cirrhosis. For these reasons other major surgical procedures used in the treatment of ascites are limited in their application.

The insertion of the button is a simple procedure which may be done under local anesthesia, although spinal anesthesia was used in these cases. The site selected may be over either the right or left rectus

muscle below the level of the umbilicus. A 6 cm. midrectus incision is made and deepened through the muscle layer to the peritoneum, which is nicked to allow the insertion of a suction tube to remove the ascitic fluid. The opening in the peritoneum is then enlarged to the same length as the skin incision, and the subcutaneous fat layer is freed over an area of about 10 cm. below the lower margin of the wound. After downward retraction of the skin and fat layer and upward retraction of the peritoneum and anterior rectus fascia, a stab wound is made about 4 cm. below the lower margin of the wound, going through the anterior rectus fascia, muscle and peritoneum. The button is inserted through the stab wound and is fixed to the peritoneum by a silk purse-string suture. The rectus fascia is fixed to the button in a similar manner after placing the rectus muscle between the flanges of the button. The main wound is then closed in layers without drainage.

The avoidance of repeated paracenteses is the purpose of the abdominal button. The method has an other advantage in that it returns to the patient his own ascitic fluid with its protein content. The data and results in 6 cases in which the abdominal button was used are tabulated. There were 5 cases of Laennec's cirrhosis and 1 case of chronic constrictive pericarditis. Results were considered good in all cases but one. The button appeared to function in all cases.

JOHN L. LAMBERT, M.D.

Gage, M. and Floyd, J. B., Jr: Unnecessary Abdominal Operations for Pathological Lesions of the Genitourinary Tract. *Surg Clin N America*, 9:6 26 247

The clinical manifestations of lesions in the genitourinary tract often mimic disease of other abdominal organs. The author cites several reports from the literature to confirm this statement and to illustrate that from 25 to 30 per cent of patients with pathological lesions of the kidneys, ureters, or both, have had previous laparotomies for nonexistent lesions of the abdominal viscera.

The chief symptom of both intra-abdominal lesions and urologic diseases is pain. The sympathetic nerve supply to both groups of viscera is traced through the celiac ganglion and plexus so that pain from either may be widespread because of the migration of the somatic and sympathetic receptive fibers. Another source of confusion arises from the close association of the parietal peritoneum and the genitourinary tract. Pain is produced by abstraction of any sort in either the ureter or the genitointestinal tract.

Since almost any disease of the genitourinary tract from the kidneys and perirenal tissues to the bladder, prostate and seminal vesicles may simulate other intra-abdominal disease, an accurate differential diagnosis is the first requisite to avoid unnecessary operation. A careful history and physical examination supplemented by selected laboratory procedures are essential for arrival at a correct diagnosis.

The symptoms of acute lesions of the genitourinary tract are characterized by sudden onset. The fever is often higher and the pulse rate lower than in other abdominal lesions. The white blood cell count is higher and more stable in urologic disease. Nausea and vomiting are less common. Muscle spasm is of greater diagnostic importance than is pain or tenderness. If there is obstruction to the ureter the x-ray may show no abnormalities in the early stages of the illness. Certainly a routine study of the same is essential in any patient with abdominal pain. Simple x-ray studies may reveal stones in the urologic tract, enlarged kidneys, or changes in the psoas shadow. The excretory pyelogram can often give enough information to eliminate an unnecessary operation. Sometimes cystoscopic examination and retrograde pyelography may be necessary.

The high incidence of unnecessary abdominal operations for unrecognized lesions of the genitourinary tract can be reduced only by constant vigilance and thorough preoperative diagnostic study.

GYNECOLOGY

UTERUS

Magère, G., Labarbe, M. and Coiquaud A. The Value of the Operation of Halban in the Treatment of Genital Prolapse with a Dominant Large Cystocele (Sur la valeur de l'opération de Halban dans le traitement des prolapsus génitaux, avec cystocèle dominante) *Bordeaux chir.*, 1945 1 and 2 3

Among the numerous operative measures advocated for the relief of genital prolapse the operation of Halban is beginning to enjoy a certain vogue, especially in Bordeaux.

This technique, devised by Halban in 1919 is specially indicated in prolapse in which a cystocele is of paramount importance particularly in young women.

Indeed, surgery is very limited for prolapse of the bladder. If one accepts the operation of Le Fort (colpodensis) which gives the best results we have only 3 different types of operations (1) anterior myorrhaphy of the levators ani (Delanglade), (2) subvesical interposition of the corpus uteri (Schau a Wertheim) and (3) vesicouterine fixation (of which the operation of Halban constitutes one variety).

Theoretically the anterior myorrhaphy of the levators is an effective operation but experience has proved that most of the time it can not be executed because the gap of these muscles at the level of the pubis is such that they cannot be brought together. Even if one is successful in bringing them together the sutures will not hold but cut through. Finally a successful anterior myorrhaphy makes a posterior myorrhaphy inefficient.

The subvesical interposition of the corpus uteri is an excellent operation. Nevertheless, as stated by Cotte, 2 major disadvantages are inherent to this technique (1) it can be performed only with a complete prolapse of the uterus and (2) it must be restricted to patients who have already passed the menopause, because pregnancy is difficult and delivery impossible when the uterus is fixed in such a fashion under the pubis.

The simple fixation of the bladder to the uterus without fixation of the uterus under the pubis seems, at first, to be restricted to cases in which the supporting structures of the uterus are intact or repaired. The result of this procedure may perhaps, not be as good as that of the subvesical operation on the other hand, it does not interfere with subsequent childbearing because the uterus is in a normal position.

This fastening of the bladder to the uterus can be accomplished through an abdominal or a vaginal approach.

a. The abdominal fixation of the bladder is a modification of the procedure of Werth who used to fasten the uterus to the peritoneum of the bladder

The operation is executed in the following steps opening of the vesicouterine pouch separation of the vaginal wall from the bladder suture of the bladder to the uterus and finally obliteration of the vesicouterine pouch.

The abdominal fixation of the bladder is indicated in cases of cystocele without prolapse of the uterus and when the uterus cannot be exteriorized through the vagina. In these instances vaginal fixation is harder to accomplish.

b Vaginal fixation is, in fact named after Halban, whose technique is reported midline incision on the anterior vaginal wall separation of the vesicouterine pouch from the bladder opening of the corpus uteri fastening of the vesical peritoneum back suturing of the vesicovaginal fascia closure of the vaginal incision and thorough repair of the relaxed pelvic floor which, of course, is a necessary part of the operation.

Amputation of the cervix, accompanied or not by the ligation of the uterine arteries is often a necessary step. The introduction of catheters into the ureters prior to the operation is a great help when the operation is performed through the abdomen.

Nineteen patients were submitted to this operation by the authors with the report of poor results in 12 per cent. Six of the patients were not available for a follow up study.

GERARD GAGNON, M.D.

Coiquaud A : Halban's Operation (An Anatomic Study of the Vesicovaginal Fascia (A propos de l'opération de Halban. Etude anatomique du fascia vesico-vaginal) *Bordeaux chir.* 1945 3 and 4 101

In the author's opinion the most interesting stage of the Halban operation is the uterovaginal fixation. He does not attach as much importance to reconstruction of the vesicovaginal fascia as does Halban and his disciples. In fact Charrier has never encountered this fascia since employing the Halban operation. On the other hand he did observe a sparse and more or less dense cellular tissue. In order to clear up this confusion between Halban's own account and the operative findings, Charrier requested the present author to make an anatomic study of the region.

The opinions of the writers who agree with Halban as to the existence of a vesicovaginal aponeurosis are cited as Cotte, Koenig and Neel. Among those who do not agree with Halban on this point are Savariaud, Violet, Koenig and Doederlein, Rieffel, Poirier, Testut, Latarget and finally Villemain. Thus, it appears that whereas surgeons generally accept Halban's description of a vesicovaginal partition between the bladder and vagina the anatomists do not recognize such a structure. Other surgeons, such as Savariaud and Charrier seem rather to confirm the findings of the anatomists. Most probably Goff is right in admitting the existence of a thin areola

layer between the anterior vaginal wall and the wall of the bladder and an analogous layer between the posterior wall and the rectum (vaginorectal fascia). These two layers unite on each side of the vagina to form the perivaginal fascia which forms a part of the endopelvic fascia. The character of this fascia renders it impossible to dissect it as a separate layer. It is illuminating that many gynecologists apply the term fascia to the muscular tunic of the vagina because grossly it resembles a heavy layer of aponeurosis.

Thus, the famous vesicovaginal fascia is probably only the peripheral and anterior portion of the vaginal wall.

A careful study of this region was made in 13 patients from 50 to 80 years of age the majority without prolapse the specimens were obtained chiefly from Villemain's laboratory. The bladder, urethra, vagina, and uterus were removed *en bloc* including most frequently the pubis in front and a portion of the rectum behind. It was concluded from these studies that (1) the bladder and vagina can easily be separated from each other especially in older women or those with some degree of cystocele (2) the 2 organs are separated by a very loose cellular tissue (3) this loose cellular tissue becomes slightly condensed on contact with the bladder and vagina (as well as with the rectum) to form a thin layer of areolar type (4) this thin layer is not possessed of any of the characteristics attributed by certain writers to a solid fascia or "vesicovaginal aponeurosis" and (5) what has appeared to some surgeons like a fascia is in the writer's opinion nothing other than a variable portion of the vaginal wall itself in the thickness of which a large number of cleavage lines are to be found. **EMMA SCRAMER MOORE.**

Spitt, S. D.: Adenomyosis of the Uterus. A Study of 52 Reported Cases and Review of the Literature. *Am. J. Obst.*, 1946, 5: 581.

A series of 52 cases of adenomyosis uteri in which the endometrium was carefully studied is presented. The preponderance of the anovulatory endometrium in this series (72 per cent) seems to indicate a definite association with this condition.

Adenomyosis uteri occurs in from 5 to 10 per cent of all myomatous uteri. The uterine wall is the site of aberrant endometrial tissue in from 15 to 30 per cent of all cases of endometriosis. Adenomyosis uteri is most common in the fifth decade of life as is endometrial hyperplasia.

Metromenorrhagia is the most common complaint, and dysmenorrhea the second most common in patients with adenomyosis uteri.

The sustained interval of nonsecretion of the endometrium is a part of the process leading to actual endometrial hyperplasia and should be classified with it. The early interval endometrium seems to occur in younger women and endometrial hyperplasia in older women, generally. Adenomyosis is associated with anovulatory menstrual cycles in a large percentage of cases, which indicates that either

hyperestrogenism or lack of corpus luteum hormone is an important factor in the genesis of adenomyosis uteri. It cannot be said definitely however which one is responsible. The high incidence of fibroids in adenomyosis uteri seems to indicate some relationship. However this association is not frequent enough to make one conclude that one factor is responsible for adenomyosis uteri and uterine fibroids.

Pelvic inflammation and ovarian cysts occur quite frequently in cases of adenomyosis uteri. However, the conclusion that these conditions are factors in the development of adenomyosis uteri does not seem justifiable. **JOHN R. WOURT M.D.**

Scheffey, L. C., Thudium, W. J., Farrell, D. M., and Hahn, G. A.: Controversial Factors in the Management of Fundal Carcinoma. *Am. J. Obst.*, 1946 52: 559.

While surgery has, and continues to play the major role in the treatment of fundal carcinoma, the question today is to what extent irradiation therapy can be relied upon as a valuable adjunct. The authors survey 150 cases seen at the Jefferson Medical College Hospital from 1921 through 1945. One hundred and four of these patients are eligible for a 5-year survival study. No patients are unimpaired.

Surgery without irradiation has played a negligible role in the authors' management of these cases. Only 8 patients were treated by panhysterectomy with adnexal removal. There are 5 survivors, 62.5 per cent. Since 1940 5 patients were treated in this manner and all have survived (from 2 to 4 years).

Radium alone, by intracavitary application, was used in 31 instances. Among the 24 patients eligible for the 5 year study there were 21 survivors, or 45.8 per cent. Age, obesity and cardiovascular disease, contraindicating surgery were the prime reasons for this type of therapy.

Thirty-seven patients were treated by means of radium plus deep x ray therapy: 36.6 per cent survived. The authors point out that many of the patients in this group had more advanced lesions.

Adequate surgery with some form of irradiation in addition was used in 21 cases. The 5 year survival rate was 37.5 per cent. These patients received either radiation preoperatively or x-rays postoperatively. The treatments were not planned and the time interval between surgery and radiation varied greatly. The adequate recovery in some cases that first appeared hopeless led to the adoption of the planned technique.

The authors' procedure in suspected cases of fundal carcinoma, is to perform a diagnostic curettage. Radium, either 50 or 100 mgm., is placed *in situ* while the curettages are examined by a rapid staining technique which permits a report in 4 hours. If they are malignant, a dosage of from 4,500 to 5,000 mgm. hours is administered. Surgery (panhysterectomy plus adnexal removal) is carried out from 8 to 10 weeks. Among 10 patients so treated prior to 1940, there were 9 survivors (90 per cent). The 1 death occurred 4 years after treatment and was due to cancer. **Dor**

ing the past 5 years, there have been 21 patients treated by this method with 20 survivals (1 to 4 years). The 1 death followed an embolism 2 years after treatment. Although there was no autopsy, no cancer was noted prior to death. Of the uteri removed after the preliminary radiation 54.8 per cent showed residual cancer.

The authors believe that this planned technique of preoperative radiation followed by adequate surgery in from 8 to 10 weeks, will give the best results in fundal carcinoma.

JOHN R. WOLFY, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Sirtori C., and Bussolati, C.: Anatomical, Histological, and Clinical Observations of Ovarian Tumors (Considerazioni anatomico-istologiche e cliniche sui tumori dell'ovale). *Tumori* Milano 1941 27 308.

The authors made a study of 80 cases of ovarian tumors observed between 1933 and 1940. 46 of which were obtained at autopsies and 34 at biopsy. It is their observation that ovarian tumors appear from the 45th to the 65th year of life, being more frequent in women who have suffered a functional derangement of the sexual glands. They find it very difficult to classify ovarian tumors intelligently.

Granulosa cell tumors (17 cases) occur at any age. Such tumors may originate from undifferentiated primitive germinal cords from the primitive cumulus oöphorus from atretic follicles (Müller) or from normal adult follicles (the latter one denied by Meyer). The authors believe that tumors consisting of immature granulosa cells originate either from primitive mesenchymal cells from germinal cords, or from the primary cumulus oöphorus, while the follicular tumors are derived from atretic follicles or mature follicles. Those tumors which have a lutein-like appearance must be considered an evolution of an adult granulosa cell tumor. Clinically the tumor causes the appearance of pubic hair in young girls while in older women there is an accentuation of the sexual characteristics (menorrhagia). There is no logical reason to distinguish between granulosa cell tumors and thecomas and it is better to refer to them as mixed tumors. The authors observed only 1 thecoma among the 17 granulosa cell tumors consequently such a tumor is rare. The granulosa cell tumors have a tendency toward malignancy in the adult and a tendency toward luteinization in younger women. Tumors consisting mostly of granulosa cells have few blood vessels while granulosa cell tumors containing many thecal cells have numerous blood vessels.

The Brenner tumor must not be regarded as a special tumor neither is it always benign as those who regard it as oöphoroma or a fibroepithelioma believe. Its occurrence in old women gives it the tendency to be a scirrhous tumor. The authors conclude that the Brenner tumor must be regarded as an epithelioma originating from aberrant epithelial rests in the ovary or in its vicinity that it may pre-

Fig. 3. Granulosa cell tumor in the luteinization stage and becoming cancerous. Observe a mixture of granulosa and thecal cell elements undergoing luteal and cancerous changes.

sent cancerous characteristics and that it may have to be considered a special aspect of the common ovarian cancer.

The seminoma of the ovary (disgerminoma) has the identical structure of the testicular seminoma. Histogenetically the tumor may originate from

Fig. 4

Fig. 4. An area of fibroma of the ovary which could be considered a thecal tumor.

Fig. 5. Papillary carcinoma. Brenner tumor

Fig. 5

Fig. 6

Fig. 6. Arrhenoblastoma. Special aspect of the seminoma type of tumor with a tendency of the cellular element toward tubular or cordlike architecture.

mesenchymal cells still undifferentiated sexually or it may be considered an error of the primitive elements which may also cause the arrhenoblastomas. This agrees with the histogenetic interpretation of Plate which follows undifferentiated germinal epithelium immature—disgerminoma in males and females less immature—arrhenoblastoma in males and females, and granulosa cell tumor in the female.

The authors discard the idea that the tumor is an epitheloma or sarcoma and regard it as a mesoblastoma. The study of their 3 cases leads them to conclude that such tumors are more frequently found in young women that the tumors are functionless (different from the arrhenoblastomas and granulosa cell tumors which lead to male or female maturity) and that histologically the tumors are in the process of evolution because next to the seminoma are found areas similar to the arrhenoblastoma of the solid homogeneous type.

The arrhenoblastomas, very rare and important tumors, cannot be associated with the property of producing masculinization because some of them do not have this function. The masculinizing tumor is made up of seminiferous-like cords, while the one deprived of such property has a tubular structure, the tubulotesticular adenoma of Pick.

Blasel and Hempel have isolated the substance causing masculinization. Removal of the tumor causes a regression of the masculine characteristics and of menstruation. This was verified in the case of a woman 36 years old who resumed all her feminine characteristics 10 months after the surgical removal of the tumor.

Other tumors e.g. the luteoma and hypernephroma, may cause more or less virilism. The luteoma originates from granulosa or theca cell tumors which have undergone luteinization. Some consider this tumor to be derived from the lutein cells, but the

case of Santi, in a woman in the menopause for 7 years, contradicts this, as the corpus luteum, being a transitory formation, is absent after the cessation of menstruation. That hypernephroma of the ovary may cause virilism is still doubted. Munro considers the corpus luteum as transitory adrenal cortex. The absence of testicular hypernephroma is not sufficient to deny the existence of ovarian hypernephroma due to aberrant adrenal cortex. The authors have not encountered any ovarian hypernephroma.

A fibroma of the ovary may originate from ovarian stroma, from a fibrosed corpus luteum, from later stitial hemorrhage, from the unilateral development of a teratoma, or from interstitial inflammatory exudation.

The authors did not have any cases of mixed tumors of the ovary. They discuss a possible classification of cysts.

They believe that it is almost impossible to classify primary carcinomas of the ovary and conclude by suggesting that all ovarian tumors should be classified according to plans, one to include the histopathologic, histogenetic and clinical criteria and the other to include only the clinical criteria.

JOSEPH M. A. PARR, M.D.

Halsel, E. V: A Review of 100 Cases of Ovarian Cancer. *Am J Obst.*, 940, 5: 435.

While considerable progress has been made in the diagnosis and treatment of uterine malignancies, this cannot be said of ovarian malignancies. With an incidence of 10 per cent of all ovarian neoplasms, and with a mortality rate that has been, and remains, appallingly high ovarian cancer constitutes a major gynecological problem.

The author has analyzed 100 cases of ovarian cancer treated at the Elizabeth Stell Magee Hospital and the St. Francis Hospital in Pittsburgh, Pennsylv-

vanis, from 1929 to 1943. Thirty five cases could not be traced while the remaining 65 cases were followed from treatment until death or present survival. Four of these patients were negroes. More than half of the patients were past the menopause although 2 were under 20 years of age. 41 per cent were nulliparous.

The insidious onset of symptoms plus the rapid progress of the tumor makes early diagnosis almost impossible. Sixty-eight per cent of the patients were considered incurable when first seen. 3 per cent were examined within 2 months of the onset of symptoms and 18 per cent within 1 month. Abdominal pain, abdominal enlargement, loss of weight and abnormal vaginal bleeding were the most frequent symptoms.

Hessel places ovarian malignancy into four clinical groups as determined at the time of operation. In group I the tumor is completely removable without gross involvement of any other structure. In group II the tumor is completely removable but with some disturbance of other structures such as adhesions. In group III the tumor is only partially removable because of extension to or near by structures which can not be removed and in group IV there is extensive involvement or distant metastases and only a biopsy may be obtained.

The degree of removability determines the survival time. Histological grading is of little value in the prognosis. Postoperative radiation is of value in that it increases the comfort and improves the psychological state of the patient but its curative value is discouragingly low.

Despite the discouraging end results in advanced cases of malignant ovarian disease the author believes that operation is worth while since even simple removal of the primary growth often enables the patient to carry on a life of usefulness in comfort some times for years.

JOHN R. WOLFE, M.D.

Romeo, M.: A Study of Pathological Associations between the Internal Genitalia and the Appendix (Contributo allo studio delle associazioni morbose fra genitali interni ed appendice). *Arch. ital.* 1942 6 133

In a previous article the author described 2 cases in which dermoid cysts of the ovary with torsion of the pedicles were associated with chronic appendicitis. He now describes a case in a woman of 27 years in which dermoid cysts of both ovaries with torsion were associated with chronic appendicitis. Histological illustrations of the findings are given.

In connection with these cases he discusses the possible reasons for such a pathological association. It has been claimed by some authorities that there is an appendiculo-ovarian ligament through which infections may be carried. Others deny this and claim that the inflammation is carried through adhesions which form between the two organs. A number of other theories are discussed and statistics showing the frequency of this association are presented.

The author concludes that the conditions are different in different cases. In some the infection is transmitted through the lymphatics of the appendiculo-ovarian ligament. In some through a newly formed network of lymphatics resulting from adhesions of the inflamed organs sometimes extra peritoneally through the subserous connective tissue and sometimes through the peritoneum.

However while this explains the transmission of inflammatory conditions from the ovary to the appendix, what is to be said of the cases in which a tumor of the ovary is associated with inflammation of the appendix? He believes that in cases in which there are adhesions between the appendix and the tumor the explanation is mechanical. The increased size of the ovary brings about such changes in the anatomical relations of the appendix that the organ becomes a point of least resistance and inflammation readily develops. In the cases in which there are no adhesions and the appendix and the ovary lie at some distance from each other he believes that the association of the two pathological conditions is a mere coincidence.

AUDREY G. MORGAN, M.D.

MISCELLANEOUS

Jacobson, C. E. Jr.: Unrecognized Obstruction of the Vesical Neck in Women. *Am. J. Surg.* 1946 335 645

Three cases of chronic obstruction of the vesical neck in women were presented in which resection of all or part of the neck was performed with satisfactory relief of the symptoms.

Attention was drawn to the facts that the condition is not infrequent and that dire consequences in the form of dilatation of the upper urinary system may ensue if treatment is not instituted early in the course of the disease.

A search for the presence of early obstruction of the vesical neck in every case of chronic cystitis in women is urged so that this condition may be recognized and adequate treatment instituted.

CHARLES BARON, M.D.

Cottalorda, J. and Garmandou, F.: Intraperitoneal Hemorrhages of Genital Origin. Not Including Ectopic Pregnancy (Les hémorragies intrapéritonéales, d'origine génitale en dehors de la grossesse extra-utérine). *Gyn. obst. Par.* 1946 45 150

Intraperitoneal hemorrhages of genital origin of nonovarian source are rare. They include rupture of a vein of a subserous fibroid, strangulation of the pedicle of a pedunculated fibroid or hemorrhage in the course of a chorionepithelioma. Much more frequent than these are hemorrhages of ovarian origin. These may be either from a corpus luteum or from a graafian follicle, or from rupture of an ovarian cyst. Lastly menstrual blood may regurgitate into the peritoneal cavity via the tube. 4 cases of the last type having been observed by the authors. Corpus luteum hemorrhages occur shortly before menstruation. follicle hemorrhages in the middle of the men-

strual interval, while effusions of menstrual blood into the peritoneum naturally coincide with the menstruation.

The symptoms are sudden severe pain irradiating to the anus and lower abdominal region, sometimes accompanied by nausea and vomiting. Systemic signs like shock, weak pulse, and anemia are never observed. In most cases the pains clear up after a few hours. Often, the same kind of attack may be repeated after a 4 weeks interval. As the symptoms are rather dramatic in the beginning, it is often difficult to rule out ectopic pregnancy or torsion of the adnexa, normal or diseased.

If as often occurs surgery is done under the wrong impression of an ectopic pregnancy or torsion of the adnexa, the management should be as conservative as possible in cases of effusion of menstrual blood, ligation of the tube in hemorrhages of follicles or corpus luteum, suture of the bleeding structure.

In most cases it should be possible to differentiate the ovarian bleedings from ectopic pregnancy without laparotomy. They should be treated by hormonal therapy rather than by surgery.

WERNER M. SOLKRE, M.D.

Casimiro, G. N.: Kidney Cysts in the Field of Gynecology (*Le cisti renali nel campo ginecologico*). *Arch. ital. gine.*, 942, 6, 428.

The medical literature reveals many cases in which a diagnosis of gynecological cyst, especially cyst of the ovary has been made when the cyst was really of the kidney. This error may be due to the fact that the kidney is congenitally dystopic or there is an acquired ptosis of the organ, which brings the cyst in close relation to the ovary. This possibility should always be borne in mind by gynecologists in making a diagnosis of cyst of the ovary. They should have an accurate knowledge of the comparative frequency of gynecological and renal cysts and know that it is often impossible to make a differentiation between them from the history and clinical symptoms. Contrary to general belief, such cysts of the kidney often do not cause pain in the kidney region nor abnormalities in the urine. Nor does simple roentgen examination always suffice for differentiation. In all cases of doubt a pyeloureterographic examination should be made.

A case is described in a woman of 64 years in which the attending physician had made a diagnosis of cyst of the ovary. Suspicion was aroused by the fact that the patient had had a history of floating right kidney for some years, and ascending pyelography showed the right kidney to be ptotic and displaced to the left. The rhythm of evacuation of the urine was normal excluding hydronephrosis, and the tests for hydatid cyst were negative. A diagnosis of solitary serous cyst of the right kidney was made and confirmed on operation.

The author believes that the best operation for such cysts is subtotal resection of the extrarenal part of the cyst and leaving a border to be fixed into the abdominal wound (marsupialization). Some author-

ities hold that this method gives rise to recurrence, but if the inner surface of the cyst is cauterized with gauze soaked in 10 per cent zinc chloride any remaining epithelium is destroyed and recurrence prevented. In exceptional cases in which there is destruction of almost the whole of the kidney parenchyma, nephrectomy is indicated.

ANDREY G. MORSE, M.D.

Candido, R.: Clinicostatistical Study of 84 Cases of Hydatidiform Mole (*Rilevi clinico-statistici su 84 casi di mola vescicolare*). *Arch. ital. gine.* 1944, 6, 80.

In 56 of 21,534 pregnant women, hydatidiform mole was observed. A ratio of 1:385, which is higher than that cited by the majority of authors. Of the 56 patients, 29 were younger and 27 older than 35 years.

The cycle of fecundity can be divided into 3 periods: functional consolidation, stability and functional diminution. Thirty-seven and five-tenths per cent of the author's material was observed in the first period, in women from 15 to 27 years of age; 29 per cent occurred during the second period, in women from 28 to 39 years of age; and 34 per cent was found in the third period, in women older than 39 years. Fifteen per cent occurred in primiparae and the greatest frequency of mole was recorded in women having had from 4 to 6 deliveries.

In 21 per cent of the patients the past history revealed certain diseases such as typhoid fever, diphtheria, nephritis, cholecystitis, cardiac insufficiency and pulmonary disease, but inasmuch as in many cases a relatively long period of time elapsed between the disease and the appearance of the mole, the rôle of the preceding illness in the genesis of the mole was rather questionable. In 24 cases in which a Wassermann reaction had been performed, negative results were obtained. In 5 cases the mole became manifest during the second month of amenorrhoea; in 19 during the third month; in 28 during the fourth month; and in 4 during the fifth month.

The anatomopathological study showed that in only 3 cases or 4 per cent of the entire material, the degeneration was partial, while in all of the remaining cases the development of hydatidiform mole was complete.

Fatal hemorrhage occurred in 3 cases, or 6 per cent of the entire material. In 1 case a benign mole and in 2 cases, a destructive mole was present.

Albuminuria was noticed in 15 patients, or 27 per cent. In 9 patients, or 16 per cent, a chorioepithelioma developed. Malignant degeneration of a mole occurs with greatest frequency at the ages between 25 and 30 years.

In 10 cases, or 19 per cent of the author's material, a spontaneous expulsion of the mole took place. In 43 cases, or 91 per cent, a curettage and in 4 cases, or 9 per cent, a hysterectomy was performed.

Endometritis seems to play an important rôle in the pathogenesis of the mole.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Schneider P : Distal Ectopic Pregnancy Implantation of the Ovum in the Cervical Mucosa. *Am. J. Surg.* 1946 73 376.

In the present article, the author quotes the opinions of authorities, attesting to the rarity of true cervical implantation of the ovum. He reports 1 case of this condition.

The author states that there have been only 12 proved cases, and 7 cases in which he believed the condition was clinically possible. There are 11 additional cases in which the placenta involved the corpus, isthmus, and cervix. Finally there are 3 reported cervical abortions.

True or primary cervical implantation is restricted to those cases in which the site of the placenta lies entirely within the cervix. The author defines the cervix as that portion of the uterus which lies between the external and internal os. A complete histological description is made of the three divisions of a pregnant and nonpregnant uterus. The 12 proved cases are described. The chief histological difference between the abnormal and normal implantation is the absence of the intervening decidua. Decidual cells may occur singly and in groups, but these may not be compared with the normal decidua. The decidua basalis limits the destructive action of the villi. However in ectopic pregnancies the villi destroy the underlying structure. This is more pronounced in cervical implantations than in tubal pregnancies or placenta accreta.

The pathological description of cervical implantation is excellent. Clinically the only constant observation was violent hemorrhage that in all cases led to active intervention. In only 2 cases was the correct diagnosis made. The condition has been diagnosed as incomplete abortion, bleeding varicosity chorionepithelioma, and ruptured tubal pregnancy.

Treatment is variable depending upon the amount of bleeding, the location and duration of the implantation. Intracervical packing or some form of surgery was used in nearly all cases. Several late severe secondary hemorrhages occurred.

JAMES F. DOORFELLY, M.D.

Armand, M. F. : The Intravenous Administration of Magnesium Sulfate as the Exclusive Treatment for Eclampsia (Traitement exclusif de l'éclampsie par le sulfate de magnésium en voie intraveineuse). *Obst. gyn. int. amer.* 1946 4 410.

Accepting the assumption of F. C. Irving that eclampsia is not a primary disease of an organ but a state of spasm of its terminal arterioles, the author concludes that the only rational therapy of this condition involves the administration of antispasmodics. Following a review of the literature on the use of

morphine and of magnesium sulfate in the treatment of eclampsia, he discusses the significance of changes in water metabolism in eclampsia, and the effect of water retention in creating spasms of the terminal arterioles. The vascular spasm slows the blood stream, produces edema, increases the viscosity of the blood, and finally causes ischemia of the tributary organs of the vessels involved which explains the clinical picture of pre-eclampsia and eclampsia.

The antispasmodic effect of magnesium sulfate diminishes the nervous irritability and rapidly and definitely diminishes the contractility of the smooth muscles. The blood pressure falls almost immediately and the circulatory equilibrium is restored. Diuresis is augmented. Frequently micturition occurs shortly after the injection and the attack is interrupted. Magnesium sulfate is also said to have an anesthetic effect without reduction of the alkaline reserve of the blood.

Results obtained with the intravenous administration of magnesium sulfate by the author have been so good that he believes this is the specific treatment.

A 50 per cent solution of magnesium sulfate is employed and the dose consists of 5 gm. of magnesium sulfate, or 10 c.c. of a 50 per cent solution. Should the attack recur a new injection of 2.50 gm., or 5 c.c. of the solution, may be given every 4 hours until return to normal. If the patient, although apparently normal, continues to suffer from headaches or cramps, or if the blood pressure shows a tendency to rise, a daily injection of 5 gm. should be given.

The total amount of the salt which can be injected without danger depends upon the severity and duration of the attack. In the 27 cases treated by the author the attack was cut short in 3 cases with 2.5 gm. of magnesium sulfate, in 7 with 5 gm., in 1 case with 7.5 gm., in 4 cases with 10 gm., in 3 with 15 gm., and in 1 each with 25, 30, and 50 gm. respectively. As a rule, 5 gm. of the magnesium sulfate, or 10 c.c. of the 50 per cent solution, suffice. Frequently a result may be achieved with less, and rarely is a much larger dose needed. In the presence of recurring attacks and deep coma, one should not hesitate to repeat the injections up to from 30 to 50 gm. If, on the other hand, the patient responds nicely to the first injection further administration is contra-indicated since under these circumstances the resulting withdrawal of water from the brain might lead to acute dehydration of the brain and convulsions.

The solution is mixed with an equal portion of blood withdrawn from the vein and the injection should be made very slowly. As a rule, the injection is well tolerated and there is only a slight sensation of warmth. Occasional excitement can be controlled by interrupting the injection for a moment and then continuing it more slowly. The injection is followed by abundant perspiration and, after a quarter or half hour by micturition.

In the present series of cases the blood pressure fell immediately from 3 to 6 cm. Hg. No other treatment is required. Venesection and the use of soda

Nineteen of the 37 cases in the present series were treated exclusively by the intravenous administration of magnesium sulfate with recovery in all and no maternal deaths or complications. There were 18 primiparas and 3 multiparas. Five women were seen during pregnancy 4 in labor and 13 in the puerperium. In the 4 patients in labor, delivery was spontaneous. Two patients were admitted with fetal retention and 2 others gave birth to living infants. In the 5 patients seen during pregnancy the pregnancy proceeded normally but only 3 infants survived. The series is too small to permit of definite conclusions, but the results are sufficiently encouraging to warrant further trial of this very simple method of treatment.

Enns Schwartz Moore.
Hazelund, J., and Hedenstedt, S.: Investigations of the Permeability of the Placenta with the Help of Elliptocytes. *Acta med scand* 1945 Supp. 170, p. 135.

According to the conception generally prevalent the maternal and fetal vascular systems of the placenta are completely detached from one another so that no direct transition of blood from the mother to the fetus, or vice versa, is possible. The authors believe that a leakage can sometimes occur in the placental septum and permit substances which do not permeate under normal conditions to pass over from the maternal vascular system to that of the fetus. This hypothesis may explain some of the complications of pregnancy as in erythroblastosis fetalis. Two investigations on the permeability of the placenta are described.

In the first experiment a transfusion of elliptocytes blood was given to a normal pregnant woman shortly before the onset of labor. No rise in the elliptocytic content of the child's blood was noted after birth. A similar transfusion given to a patient with nephropathy gravidarum resulted in a definitely increased elliptocytic content of the child's blood immediately after birth which gradually decreased in the next few days.

Hazelund, J., and Nylin, G.: Investigations on the Permeability of the Placenta with the Aid of Red Blood Corpuscles Tagged with Radio-Active Phosphorus. *Acta med., scand* 1946 Supp. 170 p. 350.

This is a report of the second group of investigations of the permeability of the placenta. Red blood corpuscles from the mother tagged with radioactive phosphorus were reinfused before parturition. In 5 normal patients no labeled blood corpuscles were found to pass through the placenta into the blood of the newborn child. In the sixth patient, whose pregnancy was complicated by asthma, there was a significant increase in the amount of labeled, radioactive red blood corpuscles in the newborn child.

The results of these experiments indicate that under certain conditions maternal red blood cells can pass through the placental membrane into the fetal vascular system.

George Buxner, M.D.
Lock, F. R. and Myers, R. T.: Endometriosis in Association with Pregnancy. *Am J Obst* 1946 53 556.

Although the information contained in the medical literature leads one to believe that the combination of pregnancy and endometriosis is a dangerous one, the authors report 2 cases in which patients treated conservatively for endometriosis subsequently conceived and had a normal prenatal course, delivery and puerperium.

Few specific case reports of uncomplicated pregnancies in patients with endometriosis are to be found, but a careful search of the literature reveals that such cases are mentioned casually in articles which deal primarily with the gynecological aspects of endometriosis.

An analysis of 5 of such articles shows that approximately a third of the patients who are treated conservatively can successfully conceive and indicate that the vast majority of such patients have a normal pregnancy. For this reason the desirability of employing procedures which conserve the child bearing function in youthful patients with endometriosis is emphasized.

Martini J. L.: The Demelin Forceps: 8½ Ten Years of Experience in the Pedro A. Pardo Maternity (El fórceps Demelin 8. Diez años de experiencia en la Maternidad "Pedro A. Pardo"). *Obst gín lat am* 1946 4 349.

The author describes the experience of 10 years with the use of the Demelin 8 forceps—533 applications from 1935 to 1945. The forceps weighs 650 gm. Its total length is 40 cm. Length of the blade 175 mm. Length of the handle 225 mm. Maximum width of the blade 47 mm. Maximum width of the window 147 mm. Length of the fenestra expanding in the blade 177 mm. Width of the fenestra in the plane 120 mm. Width of the cuffs 9 mm. Cephalic radius of the articulation when forceps is mounted, 160 mm. The terminal portion of the blades from the window to the beak has the form of a U and the symmetry of the axis at this level permits easy determination of the axis of the blade the axis prolonged behind indicated by the general axis of the instrument once mounted. This feature is not found in the forceps of Tarnier or Levier, in which the cuffs are asymmetric. Fenestration of the handles make it lighter and except for a little more pronounced cephalic, pelvic and perineal curvatures the forceps is almost straight. Demelin gives great importance to the in curving below the extremity of the handle so that the bar of articulation situated in the plane of the

LABOR AND ITS COMPLICATIONS

Martini, J. L. The Demelin Forceps 8; Ten Years of Experience in the Pedro A. Pardo Maternity (El fórceps Demelin 8. Diez años de experiencia en la Maternidad "Pedro A. Pardo") *Obst. gín lat* 1946, 4 339.

The author describes the experience of 10 years with the use of the Demelin 8 forceps—513 applications from 1935 to 1945. The forceps weighs 620 gm. its total length is 40 cm. length of the blade, 175 mm. length of the handle, 235 mm. maximum width of the blade 47 mm. maximum width of the window 28 mm. length of the fenestra expanding in the blade 147 mm. length of the fenestra in the plane 120 mm. width of the cuffs 9 mm. cephalic radius of the curvature, 170 mm., length of the bar of articulation 177 mm. and the distance separating the two screws of articulation when the forceps is mounted 160 mm. The terminal portion of the blades from the windows to the beak has the form of a U and the symmetry of the cuffs at this level permits easy determination of the axis of the blade, the axis prolonged behind indicating the general axis of the instrument once mounted. This feature is not found in the forceps of Fenestrator in which the cuffs are asymmetric and perineal curvatures the forceps is almost straight. Demelin gives great importance to the curving below the extremity of the handle, so that the bar of articulation situated in the plane of the

axis of the blades constitutes one-fifth of the curvature and assures that both blades are in front of the other which impedes tangential escape of the head. The first absolute general principle is to employ the least possible force. Introduction of the blades, articulation, and extraction should be accompanied by the usual precautions as in any other forceps application.

The long blades of the Demelin 8 (from 0.125 to 0.15 m. instead of 0.05 m.) act like a kind traction that attenuates considerably the bumps and rubbings by the incidence of very oblique pull on the resistant walls of the pelvic cavity whereas shorter blades accentuate the contacts between the pelvic walls and the presentation by reason that the angle of incidence (of the blades to the fetal part) approximates much more the straight short arm of the lever. The almost straight blades of the Demelin 8 adapt perfectly with the presentation and the soft parts herniating by the windows. This ample cephalo-instrumental contact permits a secure hold which is impossible if the blades only depend on their beaks like in the divergent forceps.

In the last 10 years, there were 17 008 deliveries with 533 Demelin 8 forceps applications, 88.55 per cent (472 cases) in primiparas 8.06 per cent (43 cases) in secundiparas and 3.39 per cent (18 cases) in multiparas 54.98 per cent of the patients were below 30 years of age while 40.02 per cent were above that age.

The causes for intervention were fetal suffering in 60.03 per cent of the cases prolonged expulsive period in 40.52 per cent failure of rotation in 29.83 per cent dystocia of contraction in 23.62 per cent perversion of rotation in 3.17 per cent maternal exhaustion in 2.43 per cent, eclampsia in 2.25 per cent, prophylaxis in 2.06 per cent, amniotic infection in 1.68 per cent, relative narrow pelvis in 0.56 per cent vaginal diaphragm in 0.56 per cent, polypiform edema

of Rouvier in 0.27 per cent, and excessive fetal volume in 0.18 per cent.

There were 76 episiotomies, 14.07 per cent of the total interventions. There was only 1 face presentation the rest were all vertex presentations. The 3 maternal deaths are not accounted for by the forceps hence the maternal mortality may be said to be nil. With respect to the maternal morbidity it occurred as follows: In first degree perineal lacerations, 18.33 per cent or 98 cases in second degree, 4.69 per cent or 25 cases in third degree, 0.93 per cent or 5 cases; in vaginal mucosa lacerations, 1.50 per cent or 8 cases in vulvar mucosa lacerations, 0.18 per cent or 1 case in cervical laceration, 0.18 per cent or 1 case, in shock 0.36 per cent or 3 cases in vulvovaginal thrombus, 0.18 per cent or 1 case in febrile postpartum, 6.19 per cent or 33 cases and in afebrile puerperium, 2.43 per cent or 13 cases. In the 533 interventions death occurred 36 times or in 6.75 per cent. Applications in the superior strait give a mortality of 33.33 per cent in the inferior strait, one of 6.73 per cent and in the excavation, one of 5.03 per cent. As to the fetal morbidity only benign lesions were observed, generally ecchymosis of the cheeks and scalp, never serious traumatism as caving in or fractures of the parietals, nor ocular lesions, or facial paralysis. In conclusion, the Demelin 8 is a convergent forceps almost straight, with double posterior articulation, with traction passing by the center of mobility of the head, realizing a solid and symmetrical application, respecting the spontaneous mobility of the head, scarcely traumatizing, and requiring less force for extraction in comparison with other types of forceps. Its maternal mortality is nil, the low traumatic maternal morbidity consisting mostly of benign lesions of the perineum its maternal infectious morbidity is also low its fetal mortality is 6.75 per cent and its fetal morbidity is practically nil.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Broster L. R. and Gardiner Hill II: Addison's Disease Successfully Treated by a Graft. *Brit M J*, 1946 2: 570.

Broster and Gardiner Hill describe the case of a young woman in whom a diagnosis of Addison's disease was made 9 months previously on the basis of the clinical and biochemical findings. An adrenal gland from a patient with the adrenogenital syndrome was grafted and as a result the symptoms and signs of Addison's disease disappeared. Tests by means of the withdrawal of sodium chloride showed that her blood sodium no longer was below normal and at the last test, 14 months after operation no substitution therapy with sodium chloride was required.

The tumor of the gland was from a 21 year old woman who had hirsuties, adrenal virilism, hallucinations, and depressions and who excreted 295 mgm. of ketosteroid daily. The left adrenal gland was used. It was hypertrophied to 2 to 3 times its normal size. Its large unbranched vein was cut long. The vein was perfused with heparin solution and the graft was placed in normal saline solution.

In the recipient an incision was made along the outer border of the left rectus muscle. The rectus was retracted medially. The deep epigastric artery and vein were exposed and cut medially. The wound was bathed in heparin solution, and the artery and vein were separately piloted into the adrenal vein and anchored. The recipient menstruated unexpectantly on the second day after the operation.

During subsequent examinations the graft was palpable and tender, especially before and during a period. The patient's blood pressure rose to normal or even hypertensive levels, the pigmentation disappeared almost completely, and the sodium chloride level did not diminish even when substitution therapy was omitted. The authors believe that the cortical deficiency was corrected by the graft and that they maintain that a cure was obtained 14 months after operation.

DAVID ROSENKLOOF, M D

Fine, J. Frank, H. A. and Seligman, A. M.: The Treatment of Acute Renal Failure by Peritoneal Irrigation. *Ann Surg*, 1946, 124: 857.

The authors believe that certain types of acute renal failure need not be fatal if the period necessary for repair can be provided by utilizing an extrarenal pathway as a temporary substitute for the normal excretory function of the kidney. The peritoneal membrane has long been recognized to be an excellent dialyzing membrane readily permeable to water and crystalloids. Peritoneal irrigation makes use of this dialyzing capacity for the removal of diffusible substances from the plasma and ultimately from the extracellular fluid.

Fig. 1 (Fine et al.) Diagrammatic representation of the circuit for continuous peritoneal irrigation. (Courtesy of J B Lippincott Co.)

It has been determined in the dog that adequately conducted peritoneal irrigation would provide as much as from 40 to 75 per cent of the normal renal function.

The authors describe in detail their method, and the peritoneal irrigation apparatus employed (Fig. 1). The irrigating fluid is a modified Tyrode's solution to which is added the sodium salt of heparin, penicillin and sodium sulfadiazine. Heparin is used to prevent the formation of fibrin and intestinal adhesions. Penicillin and sulfadiazine are employed as a prophylaxis against infection. The sodium sulfadiazine should be omitted if renal sensitivity to sulfonamides is present or suspected. Protein is not employed because edema of the peritoneal membranes does not occur as a result of irrigation. When the fourth reported case of gelatin is employed because the human albumin impracticable, although probably to a pH of 7.5 with concentrated sodium hydroxide. The flow of fluid is illustrated in Figure 1. Under local infiltration anesthesia the inflow and outflow tubes are inserted into the peritoneal cavity through a small incision in each flank. The stainless steel sump drain is directed into the cul-de-sac of Douglas for drainage. This type of drain obviates the plugging of the tubes as long as fluid is kept running in.

Collateral therapy is necessary for maintaining nutrition and water soluble vitamin requirements, for correcting anemia, acidosis, hypoproteinemia, and for the management of concomitant disease. The authors admit and stress that this interesting therapeutic method is still in the experimental phase. They have to date established (1) that properly per-

formed peritoneal irrigation can eliminate all clinical and chemical evidences of uremia. (3) that significant clinical improvement may occur in from 36 to 48 hours. (4) that the total time required will vary with the duration and severity of the uremic state, the degree of saturation of the tissues with the retained products, the degree of dehydration or edema, the nutritional state, the food intake, the rate of protein catabolism, the presence of concomitant disease, and the rate of efficiency of the peritoneal irrigation. (5) that irrigation does not exert a deleterious effect on the peritoneal structures, and (6) that the efficiency of irrigation so far as blood urea clearance is concerned does not diminish with time and exceeds the minimal degree of renal excretory function (10 to 15 per cent) necessary to avoid the reaccumulation of nonprotein nitrogen of urea.

The time necessary for repair of the kidney injury and recovery of sufficient kidney function cannot be forecast; this will vary from one type of injury to another and from case to case with the same type of injury. Lesions that are capable of repair in the course of a few weeks should respond to this form of therapy because it probably can be maintained safely that long. To date this form of therapy had been maintained for 12 days.

The chief hazard is the possibility of the development of peritonitis. This danger has been minimized by the introduction of a bacterial filter on the inlet side of the irrigating system, with chemotherapy and with careful quarantine of the abdominal wounds and tubes by proper dressings. The peritoneal drainage fluid has yielded the following bacteria: the *Escherichia coli* in 2 cases without significant clinical effects, and the *Escherichia coli*, *Clostridium welchii*, *Staphylococcus albus*, and enterococci without peritonitis in 1 case, as evidenced at autopsy. The inflow and outflow tubes should be so placed that dislodgment necessitating subsequent replacement should not occur. It is highly important to observe the fluid and electrolyte balance.

Pulmonary edema occurred in 75 per cent of the cases because of the intravenous administration of fluid in excess of tissue requirements for fluid in anuria and because of the presence of acidosis. The fluid requirement during anuria consists only of the amount of the water lost by evaporation which is about 1,000 c.c. daily unless fever, diarrhea, vomiting or sweating are also present. Intravenous fluid is necessary as a vehicle for glucose and amino acids. Glucose in amounts of from 100 to 300 gm. daily will satisfy the caloric needs and will prevent acidosis as the peritoneal irrigating fluid contains 2 per cent dextrose solution.

Unfortunately the proper time for peritoneal irrigation has not yet been established because it is impossible to determine the precise existence of irreversible damage. It should be begun after the onset of full blown uremia, and discontinued following the return of sufficient renal function to prevent azotemia and to sustain a normal fluid and electrolyte balance.

In the discussion of this paper before the American Surgical Association, E. D. CHURCHILL related his experience with renal shutdown following severe trauma on the battlefields which was resistant to all known forms of therapy. He expressed a hope that peritoneal irrigation as described by the authors will prove successful in combating renal shutdown following severe trauma. A. B. MCGRAW reported a successful outcome in a child with nephrosis treated by peritoneal irrigation. A. O. WINSTON believed that the authors had established a point of departure in the therapy of anuria and uremia which will apply to surgical and medical problems, and hence the constitutes a real advance.

J. E. RHOADS and R. COLE discussed the method of external dialysis. FINE conceded that this method may prove satisfactory but objected to external dialysis because it imposes an arteriovenous anastomosis on an already seriously ill patient. He again stressed the point that peritoneal irrigation is still in the experimental stage and that it is not yet considered a satisfactory clinical method.

Alcorta, L. F., Dente, J., and Sandro, R. E.: *Renal Tuberculosis in a 6 Year Old Girl* (Tuberculosis renal en una niña de 6 años). *Rev. argent. med.* 1944, 3: 594.

A case of renal tuberculosis in a 6 year old girl is reported by the author because tuberculosis of the kidneys is rare at that age. According to the statistics, children younger than 10 years form only 0.4 per cent of the entire material operated on for tuberculosis of the kidneys.

The patient was admitted with complaints of polyuria and nocturia of 1 year's duration. There were no pains in the lumbar or bladder region and palpation of the kidneys did not provoke any painful sensations. A flat picture of the abdomen showed an abnormally large shadow of the right kidney while an excretory urogram furnished the typical picture of right pyonephrosis. Roentgenograms of the chest revealed calcified residues of a primary infection. The urine was turbid and gave an alkaline reaction. The sediment contained numerous leucocytes. The bacteriologic examination established the diagnosis of tuberculosis.

The involved kidney was removed and the histological diagnosis of the specimen was found to be follicular and caseous tuberculosis. The patient made an uneventful recovery.

JOSÉPH K. KADAT, M.D.

Voltschavskii, A. B.: *A New Method of Suturing the Renal Pelvis in Pyelotomies*. *Vruchensk. Delo* 946, No. 6, 347.

After the kidney has been exposed, the pelvis is closed, and the stone removed in the usual manner, the edges of the incision are seized by Pen or Kocher forceps, one on each margin, and brought together so as to approximate the two wound borders at this point. A fine catgut suture is then compe-

lated over the ends of the two forceps and tied so as to produce a perfect approximation of the mucosal edges. A varying number of these ligature sutures (1 to 3) corresponding to the length of the incision may be applied. Care is taken to grasp only the outer layers of the incision and avoid the mucosa. However in difficult conditions such as pyelotomies *in situ* the entire thickness of the wound edge with perhaps some of the mucosal surface of the renal pelvis cavity may be inclosed. A row of suture burying this first row may be applied to the surrounding fatty tissues.

The author employed this method in 10 pyelotomies and found that the wound healed uniformly in from 2 to 3 weeks. He claims the following advantages for his method.

The suture by ligation removes the danger of hemorrhage in pyelotomies and the possibility of injury to the renal blood vessels which pass close by. Technically the method is much easier than the usual manner of suturing the incision so the kidneys pelvis. As the cavity of the kidney pelvis is not penetrated by the suture material, the danger of foreign body irritation from penetrating suture material with recurrence of the stone is removed. The rapid healing of the perfectly approximated wound edges forestalls invasion by infectious processes of the incised kidney pelvis.

JOHN W. BRENNAN, M.D.

Dees, J. E.: The Use of a Fibrinogen Coagulum in Pyelolithotomy. *J. Urol.*, Balt. 1946 56 371

If a soft calculus in the renal pelvis is fragmented during its removal, or if a small stone is unsuspected or is not located and left behind a recurrence of calculus disease is almost certain to follow. In many cases the x-ray shadow of a small stone is obscured by the opacity cast by a larger stone in the kidney. The interior of the kidney pelvis cannot be visualized through a pyelotomy incision and a search for the stone must be made blindly with appropriate forceps or by digital palpation. In such a search the kidney may be traumatized considerably. A small free stone may move from one calyx to another blood clot may cover a small stone so that crepitus cannot be elicited. Radiolucent stones and minute calculi may fall to show in the roentgenogram. Neither is irrigation of the renal pelvis and the use of routine x-rays of the kidney on the operating table in allible.

The authors have developed the following technique for pyelolithotomy.

At open operation solutions of human fibrinogen and thrombin are simultaneously injected into the renal pelvis filling it completely. A firm tenacious coagulum results which forms a perfect mold of the cavity of the pelvis regardless of its configuration. The coagulum is removed through the renal pyelotomy incision after coagulation and all free stones are incorporated within the clot. Coagula formed by the action of thrombin on human fibrinogen solution

fulfill most closely the theoretical requirements (1) the substance should be fluid so that it can be injected into the renal pelvis (2) it should coagulate uniformly completely and rapidly (3) the coagulum should be malleable and elastic enough to permit withdrawal of the mold of each calyx through its narrower infundibulum and to permit removal of the entire clot through a short renal pelvis incision (5) it should be noninjurious to the kidney (6) the coagulum should dissolve or disintegrate spontaneously if a particle is left and (7) the coagulable substance should be unaffected by small amounts of urine or blood. Two per cent clotting globulin produces coagulation of the fibrinogen solution in 30 to 20 times as great as that of human blood clot. The coagulum is disintegrated by urine in 6 to 24 hours. Free pelvic stones avoid fragmentation of all minimizes kidney trauma and avoids the necessity of complete surgical mobilization of the kidney but is not expected to remove a calyceal calculus larger than that of its infundibulum, or one which is imbedded or adherent to the renal pelvis wall. When severe infection is present and the urine is mucoid, preventing complete dissemination of the injected fluid throughout the pelvis and around each calculus aerosol O.T. (0.1 per cent) is used to irrigate the renal pelvis first as a wetting agent which permits better distribution of the solution.

After surgical exposure of the solution upper ureter (1) the lumen of the ureteropelvic junction is gently occluded with a suitable instrument or tape (2) a 4 mm. incision is made in the renal pelvis (3) a 12 F. rubber catheter with two eyes is introduced into the pelvis until the second eye lies just within the pelvis. It must fit snugly one end being clamped. If necessary and urine is aspirated from the pelvis (4) the pelvis is calibrated by distending it with normal saline solution (5) the pelvis is lavaged with 0.1 per cent aerosol solution in amounts not exceeding two-thirds of the capacity if considerable infection is present (6) the pelvis is lavaged with fibrinogen solution and is aspirated (7) fibrinogen solution and is aspirated of the predetermined pelvic capacity is injected into the pelvis (8) simultaneously by means of a small syringe and needle an assistant injects one tenth the amount of the pelvic capacity of a per cent clotting globulin through the wall of the urethral catheter into its lumen so that the two materials are intimately mixed as they enter the renal pelvis. (9) 4 minutes are allowed to elapse (10) the urethral catheter is removed and the small pyelotomy incision is enlarged and the coagulum is slowly but firmly withdrawn. The pyelotomy incision is closed completely.

The authors had perfect results in 18 cases and partially satisfactory results in 6 cases. The treatment failed in 1 case. Illustrations showing the gross appearance of the clot are presented.

DAVID ROSENBLUM, M.D.

Howard, F. S.: Instrumental Perforation of the Ureter. *J. Urol. Balt.*, 1946 56 319.

Eight cases of proved instrumental perforation of the ureter are reported. The condition is probably more common than the small number of proved cases reported might indicate.

When the rent in the ureter is small and there is no ureteral obstruction below it, there is ordinarily no untoward reaction to the injury, and the patient readily recovers without surgery. However a very serious state of affairs may be reached if there are complicating urological conditions or if the opening in the ureter is large enough to allow extravasation to continue in large amounts. Perforations by large instruments are more apt to be serious than those produced by small ones.

In itself instrumental perforation of the ureter calls for observation rather than immediate surgery. The time for drainage is determined by surgical judgment based upon the individual findings in each case. Most patients who are going on to recovery without surgical intervention are either well or nearly well 24 hours after the injury.

JOHN A. LOER, M.D.

BLADDER, URETHRA, AND PENIS

MacLean, J. T. and Gorrie, J. W.: Repair of War Wounds of the Bulbous and Membranous Urethra with Split Thickness Skin Grafts and Penicillin. *J. Urol. Balt.*, 1946 56 485.

The ideal time to repair injuries of the urethra is immediately after shock has been controlled. It is then possible to do an end-to-end anastomosis, even when there is considerable loss of tissue.

In injuries of the bulbous and membranous urethra free grafts are more practical than local flaps (Thiersch Duplay) or tubed pedicles (Gillies Davies). McIndoe, in 1937 described an improvement of this technique in which he used specially designed trochars and tubes for the insertion of the graft after a preliminary correction of the chordee. He maintained the urethra in a distended position for a period of 6 months by using indwelling gum elastic dilators. Humby in 1941 described a technique for the cure of hypospadias, in which a full thickness skin graft was built up around a catheter glued to it, and buried in the septum between the corpora cavernosa by splitting the penis longitudinally.

In the cases presented it was decided to use a combination of these latter two techniques with certain modifications.

The operative procedure is given as follows:

1. Suprapubic cystostomy. The urinary stream should be diverted by suprapubic cystostomy.

2. Exposure of the area of defect. The patient is placed in the perineal position on the table.

The anterior urethra is thoroughly irrigated with protargol 1/4 of 1 per cent, and a 24 F sound is passed to the point where it meets obstruction. Another sound is passed into the suprapubic opening through

the internal sphincter and along the posterior urethra until it meets obstruction.

An inverted perineal incision is then made, and the ischioanal space on each side is opened by blunt dissection. The median raphe is divided and the rectourethralis muscle is exposed and divided, which exposes the urethra, where the ends of the 2 sounds can readily be palpated.

An incision is made over the point of each sound, and the scar tissue between is excised.

A 24 F Foley bag catheter is then passed through the external urinary meatus, grasped as it appears in the perineal incision, and threaded on into the posterior urethra. The balloon on the catheter is distended and the catheter is withdrawn until the balloon meets the bladder neck. The exposed catheter in the perineal wound is the area of the catheter to be covered by skin graft.

3. Preparation of the urethral graft. A split thickness graft of the desired size, from 15/1000 to 18/1000 of an inch thick is cut with a Padgett dermatome from the inner aspect of the upper arm. The exposed portion of the catheter in the perineal wound is drawn further into the wound by decompressing the balloon, and the skin is placed around the catheter to form a tube. It is held in place by a few mattress sutures of 0000 plain catgut.

4. Implantation. The perineal portion of the catheter with the attached graft is then replaced, and the ends of the graft are carefully threaded into the exposed urethra at the proximal and distal ends, so that some of the graft overlaps normal urethra at each end. The seam of the tube graft should be anteriorly. No attempt is made to obtain accurate end-to-end anastomosis as any surplus portion of the graft that does not take will slough out. The catheter with its covering partial thickness graft is now in the exact position desired. The balloon on the catheter is distended with water and tied to prevent the catheter from slipping out. The urethra must be kept distended with a catheter for at least 10 weeks after the operation, then dilated at weekly intervals.

5. Closure of the perineal wound. The soft tissues are closed over the graft with a few mattress sutures of 0000 plain catgut on an atraumatic needle. A medium sized Penrose drain with a wick is inserted and brought out through the angle of the perineal wound. The wound is then closed with a subcuticular continuous running suture of No. 1 or 2 catgut.

The 36 F suprapubic McIndoe catheter is reinserted in the suprapubic wound.

6. Modification of the grafting technique. In the second case, the tube graft was built up on an intra-tracheal inflation cuff which was pulled on over the Foley bag catheter. By inflating the cuff slightly it was possible to build this portion of the urethra much larger than the normal caliber which allowed in advance for shrinkage as the healing and the surrounding fibrosis became complete.

Multiple holes were cut in the intraurethral portion of the catheter so that irrigation of the exterior

urethra could be carried out, if desired, without disturbance of the graft. JONAS A. LOFF M.D.

Levent, J: The Treatment of Hypospadias (Le traitement de l'hypospadias) *J Chir. Par.*, 1946 61 90.

Preliminary operations for the correction of a curvature or torsion of the penis may be performed on boys at the age of 3 or 4 years but a reconstruction of the urethra should not be attempted before the genital organs attain sufficient dimensions. In other words not the age of the child but the development of his genital organs is the determining factor. Usually this operation can be performed at the age of 8 years. However the operation may have to be postponed in a child with adiposogenital dystrophy. In such cases a preliminary treatment with thyroid pituitary or/and testicular extracts is indicated.

For correction of a curvature of the penis the author recommends Ombredanne's technique. It should be remembered that fibrous bands responsible for the curvature are found not only in the median but also in the lateral portions of the organ. The hemorrhage is never of any importance. After the operation the author applies extension to the penis (10 to 25 gm.) until cicatrization is complete.

The torsion observed by the author was approximately 90 degrees and in each instance to the left. For its correction he recommends a vertical incision on the right side of the root of the penis extending from above the pubic bone down to the middle portion of the scrotum. After dissection of the cavernous bodies from the pubis to the perineum a correction of the position is obtained by re-torsion and is main-

Figs. 1 and 2 (Levent) Modified Mathieu's technique. The cross sections show the glans before and after the operation.

tained by a series of sutures with a nonabsorbable material which is carried to the suprapubic fibrous tissue. The pyramidal muscle on the right side may be turned downward and attached to the cavernous bodies, but as a rule this is not necessary.

As to the reconstruction of the urethra, it is extremely important that the cutaneous flap contains no hair follicles as otherwise calcareous deposits may form. The lower surface of the penis serves the purpose very well. The diameter of the reconstructed urethra should be sufficient to permit normal micturition. To diminish the chance of a fistula formation the knots of the sutures should be placed within

the urethra. Finally, the suture lines of the urethra and the flap should be separated one from another by as much cellular tissue as possible. If this is done and one of the sutures of the urethra gives the resulting fistula closes spontaneously.

For the treatment of hypospadias of the glans or one located at the junction of the glans and the prepuce the author recommends a modified Mathieu's technique (Figs. 1 and 2).

Figures 3, 4 and 5 show the method of treatment of hypospadias of the penis employed by the author.

In hypospadias at the junction of the penis and the scrotum two stages are required for reconstruction of the urethra. First a urethral canal which leads from the scrotal meatus to the lower portion of the penis is constructed. Six months later the same procedure is employed as in hypospadias of the penis.

JOSEPH K. NARAT, M.D.

Lenowitz, H., and Graham, A. P.: Carcinoma of the Penis. *J. Urol. Balt.*, 946 56 458.

Carcinoma of the penis may begin as a relatively benign warty excrescence which at a certain stage undergoes malignant degeneration as a small neoplastic growth which after a variable period of time fissures and ulcerates, or as a scaly seborrheic or psoriasis-like patch which may not ulcerate or show its true neoplastic nature for many months or years. The differential diagnosis includes chancroid, tuberculous, balanitis, herpes proctitalis, gummatous ulceration granuloma inguinale and psoriasis.

From 1931 through 1944 the Tumor Clinic of the Veterans Administration Hospital at Hines, Illinois treated 13,490 white and 983 colored patients for all types of cancer. Of these, 100 white patients and 39 negro patients were admitted for carcinoma of the penis, an incidence of 0.66 per cent for both groups. Negro patients constituted 28 per cent of the patients with carcinoma of the penis. Of all the colored patients admitted for carcinoma of all types 3.791 per cent had carcinoma of the penis, whereas only 0.741 per cent of the white patients were admitted for this condition.

An average of 31 months had elapsed after the onset of the penile lesion before these patients ar-

rived at Hines. Previous treatment had included circumcision, local and insufficient excision of the tumor, local antisepsics or arsenicals, and insufficient radium or x-ray therapy. Two patients had undergone emasculation and total amputation of the penis with bilateral groin dissection.

Carcinoma of the penis is rare among males. We have been circumcised at birth. None of this group of 139 patients had been circumcised in infancy. It was noted that the incidence of venereal diseases had been higher in this group than in the general population but it is difficult to attribute etiological significance to this finding. The marital status was not found to be a causative factor. Irritation, trauma, injury and chronic inflammation seemed to have a definite etiological bearing. In both white and negro patients, the highest incidence occurred between the ages of 45 and 49.

The papillary type of tumor predominated over the infiltrating type in this series. The sites of origin were found to be (1) the prepuce and frenum, (2) the glans, and (3) the coronal sulcus. Metastatic spread is by way of the penile lymphatics which, with those of the scrotum, lower abdomen, and thighs, are part of one system draining into the inguinal and femoral lymph nodes. In this series, 54 patients had no involvement of the lymph nodes, 37 had bilateral involvement, while 11 had unilateral lymph node involvement. Inguinal node metastases appeared to depend primarily upon the degree of malignancy of the primary lesion and not upon the duration or the extent of involvement of the penis by the carcinoma.

There are no symptoms pathognomonic of cancer of the penis. The disease is treated by radiotherapy or surgery or a combination of these methods. A lesion 3 cm. or less and not involving Beck's fascia is treated entirely by radiation. Radiotherapy is also indicated for preoperative irradiation preliminary to surgical intervention and for palliation. Preoperative irradiation is not given to metastatic inguinal nodes because it is ineffective in clinically arresting the disease. Postoperative irradiation of the groins is effective in decreasing the incidence of recurrence and for palliation.

Adequate preoperative and postoperative care is essential. Spinal anesthesia, combined in some instances with sodium pentothal given intravenously was the anesthetic of choice in this series. Simple or partial amputation was performed on 45 patients, with bilateral groin dissection either at the same time or at a later date, according to the general physical condition of the patient. Total or complete amputation was performed on 20 patients who had extensive involvement of the penis but no involvement of the regional lymphatics. The urethra was brought out through the perineal body in preference to leaving it in the upper portion of the scrotum. Partial amputation with bilateral groin dissection was performed on 6 patients. Total amputation with bilateral groin dissection was performed in 13 cases in which the entire organ as well as the regional lymphatics were extensively involved. Esas-

culation with bilateral groin dissection was performed on 8 patients.

Irradiation alone was given to 53 patients and of these 62 per cent are alive. Major surgical procedures were performed on 83 patients and of these 42.7 per cent are alive.

A plea is made for early biopsy of all suspicious penile lesions

CLARENCE V. HODGES, M.D.

GENITAL ORGANS

Pearse, R. and Meyer E. G.: Cancer of the Prostate. *Canad. M. Ass. J.*, 1946 55 441

Cancer of the prostate ranks third in frequency being surpassed only by cutaneous and gastrointestinal carcinomas. Malignancy usually arises in the posterior lobe of the prostate gland far away from the urethra hence the lack of early symptoms but this anatomic position makes it susceptible to early detection by digital palpation through the rectum (Fig. 1)

A small hard prostatic nodule with ill defined margins felt digitally on rectal examination should arouse grave suspicion. Such a nodule may be an early carcinoma and should be differentiated from a fibrous nodule resulting from chronic prostatitis or prostatic calculi. The patient should be observed for a while during which time the serum acid and alkaline phosphatase is estimated. In case of doubt the patient should be hospitalized and prepared as for a perineal prostatectomy. The prostate gland is exposed by the perineal route the nodule excised and biopsy performed. If cancer cells are found a radical prostatectomy is performed.

When cancer is coincident with adenomyoma the problem of diagnosis becomes more difficult. It should be remembered that the cancer is not situated in the adenomyoma but in the thinned out prostate which forms the so-called false capsule of the larger benign tumor and will not be removed by suprapubic enucleation which is commonly but erroneously called prostatectomy (Fig. 2). Such cases should be treated by radical perineal operation as these patients have good prospects of cure.

The majority of patients present themselves for treatment late in the course of the disease when they experience symptoms of urinary obstruction or metastases, or both. There is no known cure for such a patient. However strikingly beneficial results follow bilateral orchiectomy performed on patients with urinary obstruction and pain from metastatic foci. The pain disappears in from 24 to 36 hours and the patient may void more freely within a week. Roentgenograms of osseous metastases will show a return to more normal bone structure in 2 to 3 months. The serum acid phosphatase, which is usually elevated drops toward a normal level and the alkaline phosphatase shows an initial further rise and then a slower recession. Many cases, however require transurethral resection in spite of orchiectomy. The same chain of events may occur when similar patients are treated with estrogens. The results of orchi-

ectomy and/or estrogen therapy are not lasting relapses may occur

It is not known why relapse occurs. It is postulated that since androgens are produced in the testes and adrenal glands the adrenals acquire a compensatory androgen activity following orchiectomy and thereby reactivate the cancer. The combined treatment by orchiectomy and with estrogen does not achieve better results than either type alone.

Estrogen therapy renders the patient less miserable and apparently prolongs life. This is considered the best palliative treatment. Whether orchiectomy is to be preferred to estrogen therapy is a matter of further research. In performing an orchiectomy it is necessary only to remove the bodies of both testes and replace the cords and epididymes in the scrotum. The epididymes are saved because they are not concerned in the production of androgens. Also the presence of something in the scrotum pleases the patients. In 3 or 4 months the epididymes atrophy but by that time the patient is already reconciled and psychologically adjusted.

Orchiectomy can be done through a small (1 inch) incision over each external inguinal ring

ROBERT TURELL, M.D.

Blasini A.: Two Cases of Seminoma in the Inverted Testicle (Due casi di seminoma in testicolo invertito). *Arch. Ital. urol.*, 1943 30 336

The author reports 2 cases of seminoma of the testis with inversion. He precedes the report with a discussion of primary tumors of the testicle in which he observes that such tumors (1) are rare and (2) may be classified as epithelial tumors, connective tissue tumors mixed tumors, and teratomas.

The seminomas he continues are to be found in the testis and in the ovary may be small in size not to exceed 100 gm., or they may weigh up to 500 gm. The cut surface of the smaller ones shows a neoplastic mass subdivided in lobules by connective tissue and in the large ones the cut surface may be studded with areas of hemorrhage and necrosis. The tunica albuginea is usually smooth in both and if invaded by the neoplasm it will ulcerate and cause a fungating neoplasm. A hydrocele is always present

Fig. (Blasini) Seminoma of the testicle. Intimate contact of the neoplastic elements with the dilated capillaries.

Fig. 2. Microscopic view of seminoma with low power.

A detailed histological description of the tumor follows. The neoplastic mass has fine fibrillary septa surrounding the individual cells, and a more abundant connective tissue stroma which causes distinct lobulation and tubular forms with transition of one into the other. The cells themselves may be round or polygonal. The cytoplasm is scanty. The nuclei may be round or oval and the mitotic figures numerous. A silver impregnating stain reveals a fine fibrillary stroma, part of a more massive one which makes the scaffold for the cell nests. Areas of hemorrhage, necrosis, and lymphocytic infiltration are present. The neoplastic tissue invades, compresses, and destroys the parenchyma of the testis.

Because some of the cells resemble spermatocytes, the tumor is classified as carcinoma by some and because of the presence of fine fibrillary network it is considered sarcoma by others. The presence of this fibrillary scaffold which embraces practically every cell has been clearly and irrevocably demonstrated by Coccarelli and Ferrera with the Bielschowski Weigert stain. This is in contradiction to some authors who would ascribe the presence of this fibrillary network due to stains.

LaManna has proved without doubt the presence of these fibrillae surrounding the acini and the individual cells, and therefore concludes that seminomas must be considered sarcomas. He also cites the radiosensitivity of the tumors which is similar to that of sarcomas, as stated by Porchownik, Auburg and Mexakawa. A discussion as to the origin of such tumors (seminoma) is then given. Most authors ascribe its origin to a proliferative perversion of the different elements which constitute the testis. Etiologically trauma is given as a first cause, and LaManna ascribes the origin of the tumor to repeated surgical interventions for hernia and hydrocele. Ectopia and hypoplasia make the tumor more common on the right side. It usually occurs before the twentieth year of age.

The tumor is of slow growth. Decreases sexual potency causes a feeling of heaviness in the erect

position but no constitutional disturbances. The growth of the tumor may displace the root of the penis. The testis is hard, smooth, mobile, and slightly painful. The epididymis is usually normal, but indurated at times. The cord is normal and the hydrocele usually contains blood tinged fluid. The inguinal lymph glands are invaded on both sides, become adherent to the skin early and soon the iliac, retrocolic, and lumbar aortic nodes are invaded. In the diagnosis, x-ray study is of importance as it may reveal metastases or a modification of the normal contour of the involved organs proximal to the suspected growth.

The Ashheim Zondeck test is always positive in malignant tumors of the genitalia and becomes negative after the removal of the tumor. The test is positive in the presence of metastases. A thorough examination of the fluid withdrawn from the hydrocele must be made.

The prognosis is poor. A seminoma of the testis not removed is always fatal therefore early diagnosis and early surgical removal are necessary. Removal of the testicle must include removal of the cord and the lymphatic glands up to the renal pedicle. (According to Chevasus from the nodes around the renal pedicle the drainage is toward the mediastinum, root of the lungs, and suprarenal gland.) Metastases occur at an early age and have been found in the mediastinum, lungs, and vertebral column.

Occasionally x-ray therapy before and after surgery may be helpful, but it is to be remembered that the tumor is exquisitely malignant, and that it is refractive to surgical as well as roentgenological treatment.

The author reports 2 cases of seminoma with the didymis-epididymus apparatus in anterior inversion. He states that the inversion may be anterior, vertical, horizontal, or lateral, and concludes that the anomalous orientation of the gland along with trauma may be the cause of the neoplasm.

JOSEPH M. A. PARK, M.D.

MISCELLANEOUS

Robinson, J. N., Culp, O. S., Snby H. I., Reiser C. W., and Mullenix, R. B.: Injuries to the Genitourinary Tract in the European Theater of Operation. *J. Urol.*, Balt. 1946 56 498.

Cross section groups of patients with injuries to the urinary tract have been studied in as much detail as the available records permit.

High explosive shell fragments were the most common missiles encountered in 100 cases of ruptured urethra the anterior urethra was injured most frequently, and the bulbous segment was the most common site of the injury. It is apparent that the treatment of choice is (a) early restoration of urethral continuity and (b) adequate urinary drainage. Very small defects may be managed satisfactorily in a variety of ways, but in the authors' cases, larger injuries did best when treated with suprapubic cystostomy a splinting urethral catheter and some type of surgical approximation of the damaged tissue. No deaths occurred in this group and 52 per cent of the patients resumed duty in the European theater of operation.

Of 100 perforating wounds of the bladder 50 were extraperitoneal defects, 30 were located intraperitoneally and 20 had both extra and intraperitoneal involvement. Shell fragments and bullets were responsible for most of these. Seventy-one per cent also had injuries to other systems, usually perforation of the intestines or fracture of the pelvis. All were treated eventually by suprapubic cystostomy in 81 cases which were recognized promptly the average time between injury and operation was 9.3 hours. Drainage of the peritoneal cavity was unnecessary and repair of the bladder defect seemed to hasten recovery but was not essential. Treatment by indwelling urethral catheter alone proved unsatisfactory. Two deaths occurred in this entire group. One patient whose condition was not diagnosed and treated until after evacuation developed peritonitis the other died of pneumonia. Eighty per cent recovered promptly while still in the ETO. Early cystostomy proved to be the most important single factor in the treatment of these patients.

Twenty-five wounds of the ureter were studied. The lower third was injured most frequently and complete division was more common than partial severance. Only 2 patients failed to have injury to other organs usually the intestinal tract. Only one fourth of the patients were diagnosed at the initial operation. Early diagnosis is imperative and may be possible only after pyelography. Proper treatment depends upon whether the defect is partial or complete. In partial rupture, although the anatomical closure of the ureteral tear is desirable extraperitoneal drainage and/or indwelling ureteral catheters often are adequate. In cases of complete division however end-to-end anastomosis over a splinting catheter with diversion of the urine is the operation of choice. One death occurred in this group of 25 patients and this was due to peritonitis following

unsuccessful repair of an associated intestinal injury. Nephrectomy should be confined to cases with massive loss of ureteral tissue and to complete failure after more conservative surgery.

Twenty-five blast syndrome kidneys recovered without surgical intervention despite secondary hemorrhages in 2 cases. Only 2 patients failed to resume duty in the theater and these were evacuated to the United States with thrombophlebitis and lung abscess, respectively. The urinary tracts were normal.

Seventy-five gunshot or shell fragment wounds of the kidney were studied. Seventy per cent also had wounds of other important structures, with the chest predominating. Sixteen had nephrectomy at the original operation and 8 required nephrectomy after evacuation to the rear. The remaining 51 had only conservative surgery. Two patients died 1 from peritonitis due to necrosis of the colon and the other from secondary hemorrhage following nephrectomy. Seventy-five per cent of the patients returned to duty in the ETO. Only when there is uncontrollable hemorrhage, evidence of increasing urinary extravasation, massive destruction or extensive infarction of the kidney is surgical intervention indicated. Operative treatment usually can be conservative with foreign body removal suture or packing of the kidney and perirenal drainage as the operation of choice. Occasionally it will be obvious that nephrectomy is necessary.

Sulfonamides and penicillin were used almost routinely in all of these injuries to the urinary tract. They seemed to prolong the safe interval prior to initial treatment and lessen postoperative complications. Transfusions of plasma and whole blood were employed frequently and undoubtedly influenced the clinical courses and end results.

JOHN A. LOFF, M.D.

Hanley, H. G.: The Female Urethra and Its Relation to Upper Urinary Tract Infections. *Proc. R. Soc. M. Lond.* 1946 39 741.

Hanley reports a study of 433 women in an attempt to demonstrate the close relationship between urethral inflammation and upper urinary tract infection in women of the childbearing age. In addition to a general and gynecological examination a full urological examination was made in every case.

Over half of the women attending the author's clinic have symptoms directly referable to the urethra, such as frequency, urgency, and dysuria. He contends that true cystitis is a relatively rare condition compared with the urethrotrigonitis which really causes these symptoms. A nonpurulent urethritis associated with normal urine is the underlying disease. The trigone is frequently affected also. The onset is generally acute, there may be acute exacerbations, and the condition may progress to a typical pyelitis.

Fifty-four per cent of the women in this pyelitis group had a history of preceding urethrotrigonitis. In acute urethrotrigonitis the onset is sudden, severe urgency and dysuria are present and only a few

drops of urine are passed at a time. Terminal hematuria is common. Occasionally dysuria without frequency is observed. There are marked constitutional effects. Usually the symptoms subside in a week. During the acute stage the urine may contain pus, red cells, and the *Bacillus coli* but the urine quickly clears. Inflammation of the trigone and urethra is present cystoscopically.

A high proportion of cases settle down into a state of chronic urethral irritability punctuated by acute exacerbations for months or years. Morning frequency and dysuria are present, associated with urgency, incomplete bladder emptying, suprapubic pressure and terminal hematuria. There frequently is referred pain to the loin, groin, thigh, and suprapubic region probably caused by an associated ureteritis. In some cases the histories went back from 8 to 10 years.

Only 3 per cent of the group gave a history of previous abortion. Normal childbirth did not seem to be important etiologically. There was a surprisingly low incidence of accompanying pelvic disease other than cervical erosion. The urine is usually crystal clear. The urethral orifice is frequently edematous and hyperemic. Narrowing of the urethral lumen was one of the commonest findings. Cystoscopy demonstrated a normal pink yellow mucosa, but a localized trigonitis, always accompanied by a similar or worse degree of pathology in the urethra, was present. At the margin of the internal urethral orifice are evident edematous, translucent, pedunculated or sessile polyps and large congested vessels. These are best seen with a foreoblique telescope or a urethroscope. The polyps appear singly or in clusters, usually between 10 and 2 o'clock, and may be

solid, pedunculated, translucent, or in rigid hillocks. These hyperplastic changes are found so often in association with the symptoms of frequency and dysuria that there can be little doubt that they are part of the syndrome.

Because of the argument that these urethral findings are so common as to be of no significance, a control series of 70 women of the same age group who had never at any time complained of abnormalities of micturition was examined. Urethral polyps and hillocks were present in only 5 of the 70 controls, but all of these 5 had had abortions or salpingitis. These figures suggest that urethral polyps are not in a previously uninfected urethra. As to the mode of infection, the first symptoms date from the time of marriage in so many cases that there is no doubt that the sexual organs are closely bound up with the etiology of the condition.

In 80 per cent of the women the first onset of urethral symptoms developed within 3 months of marriage. Not only defecation but coitus after a prolonged interval may precipitate an attack. In the majority of cases the primary acute infection is a direct ascending infection from the vulva.

The author believes that the evidence in favor of a blood-borne infection in pyelitis is not convincing and he considers ascending infection up the periureteral areolar sheath an important consideration. In periureteritis there is dull, almost continuous pain in one or both iliac fossae and groins, mild spasms of colic which are made worse or better by the onset of menstruation. The passage of a ureteral catheter may produce a dramatic cure, and frequently mere urethral dilatation suffices.

DAVID ROBERTSON, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Murray R. C., Kirkpatrick, H. J. R., and Forral, E.: A Case of Albright's Syndrome (Osteitis Fibrosa Disseminata). *Brit. J. Surg.* 1946, 34: 48

Albright's syndrome is characterized by unilateral multiple cystic bone lesions, by brown nonelevated pigmented areas of the skin which tend to be on the same side as the bone lesions by endocrine dysfunction associated with precocious puberty and by the beginning of the disease in the early years of life.

Generalized osteitis fibrosa cystica (von Recklinghausen's disease) is very similar to Albright's disease and is caused by an excessive secretion of parathyroid hormone usually associated with adenoma of the parathyroid glands. In Recklinghausen's disease generalized osteoporosis with foci of osteitis fibrosa is the predominant finding. There is also a high serum calcium and plasma phosphatase a low plasma inorganic phosphorus, and an excessive excretion of calcium by the kidneys.

In Albright's disease generalized osteoporosis is absent. The bone lesions are spotty and there is normal bone between the lesions. The plasma calcium and plasma inorganic phosphorus usually are normal. Blood phosphatase is elevated only in advanced cases. The urinary output of calcium is not increased. In female patients there is precocious puberty and early union of the epiphyses.

Some cases exhibit only one or two of the principal three symptoms of Albright's disease. Very often the disease occurs in a mild form without any extra-skeletal symptoms. The bone lesions are regularly but not exclusively found in Albright's disease.

At the site of the bone lesions the cortex is extremely narrowed and the normal structure of the

bone is replaced by irregular imperfectly calcified osteoid tissue. The outer surface of the cortex is covered by a layer of fibrous tissue. The Haversian canals are widened because of increased osteoblast osteoclast activity. The deeper portions of the bone are replaced by a matrix consisting of closely packed spindle shaped cells, small foci of osteoid tissue giant cells and irregular trabeculae. In some areas depending on the activity of the process some more mature fibroblasts are seen. There are many thin walled vessels and there is evidence of recent hemorrhages.

A detailed account is given of a patient 25 years old who was afflicted with Albright's disease. The childbirth was uneventful and the child appeared normal except for a large birthmark. The parents sisters and brothers showed no evidence of any deformity. At the age of 4 the child was noticed to be knock kneed. At the age of 9 medical aid was sought because of deformity of the lower extremities. The upper ends of the tibiae were enlarged and nodular. A wedge osteotomy of the left tibia and fibula was performed and healed normally. A year later the child sustained a fracture of the femur which healed satisfactorily. This patient was seen again at the age of 22. The deformities of the lower extremities were described as grotesque by the examining physician (Figs. 1 and 2). There was some clubbing of the left ring and middle fingers. A very large area of brown pigmented skin covering the left side of the body was also noticed. The heart was enlarged. The electrocardiogram showed inversion of the P₄ and a slight tendency toward right axis deviation. No abnormality of the reproductive system was noticed. Roentgenograms of the entire skeleton revealed lesions in many areas of the bones of the legs pelvis spine ribs, and upper extremities.

Figs. 1 and 2 (Murray et al) Photographs showing the condition of the lower limbs on admission.

The laboratory findings were normal except that the serum phosphatase showed 80 King Armstrong units and there was a trace of Bence Jones proteose in the urine on 7 occasions.

The patient had four osteotomies on the tibiae and fibulae, and both femora. The object was to bring the legs in general alignment with the hips. Two years after treatment was initiated he was able to walk with seat-bearing corset-topped calipers.

Treatment of the general condition with the object of restoring the bone to normal is usually not successful. X-ray therapy of the bone lesions and the pituitary gland did not prove successful. Helfet reported considerable success in treating generalized fibrocystic disease of bone, unassociated with parathyroid adenoma, with aluminum acetate or gluconate with the object of precipitating part of the phosphate in the bowels to prevent its absorption. Activity of the parathyroid gland is stimulated by the blood phosphates.

Various theories were cited to explain the etiology of Albright's disease. Albright advanced the theory that the symptoms are based on embryological defects. Lichtenstein and Jaffe believe that the disease has its origin in the perverted activity of the bone-forming mesenchyme. Steinberg and Joseph believe that the cause lies in faulty development. Others suggest that the disease is the result of endocrine disturbances. Burrows attributes changes of the blood vessel walls to be responsible for the localization of the foci in the bones, skin, and parathyroid glands.

George I. Rens, M.D.

Caffey J.: Infantile Cortical Hyperostoses. *J. Pediat.*, St. Louis, 1940, 29, 541.

The author reports 10 cases of cortical thickening of the skeletal system in children. His first case was observed in 1938. Three similar cases were encountered in 1939, 1940, 1944 respectively. The present communication pertains to a detailed study of 6 additional cases which the author has studied in collaboration with other clinicians.

Fig. (Caffey) Top, Lamellated thickening of the cortex of the right ulna. Left lower, Symmetrical cortical thickenings in the second, third, fourth, and fifth metatarsals of both feet. The first metatarsals, in contrast, are not involved. The phalanges were normal.

Fig. 2 (Caffey) Top, Long, thick hyperostosis in the ulna. The ulnar side of the radius is also slightly thickened. Bottom, Symmetrical hyperostoses in the fifth metatarsals. There is also some cortical thickening on the medial side of the second left metatarsal.

All of the patients exhibited the following triad: (1) tender swelling deep in the soft tissues, (2) cortical thickenings in the skeleton, and (3) onset during the first 3 months of life. There was a distinct uniformity of cortical hyperplasia under a profuse infantile periosteum. Bony predilection is unpredictable. Infantile cortical hyperostoses were demonstrable roentgenologically in the mandible, clavicles, scapulae, ribs, skull and the tubular bones of the extremities. Soft tissue swellings were deep, firm, non-fluctuant, noninflammatory and not particularly superimposed upon the bony hyperplasia in all instances.

Other less uniform manifestations were fever, pleurisy, anemia, and an increased sedimentation rate. After a variable period of weeks, and in some cases months, all patients recovered without any residual morbidity. Prolonged clinical investigation has not elicited the causative agency of this unusual entity. It is further noted that this disorder is a self-limited disease for which there appears to be no specific treatment. Eight of the 10 patients, whose onset of the disease flourished at or under the age of 6 months, exhibited facial swellings. All except 1 disclosed mandibular hyperostoses. Cortical thickening of the metatarsal bones was noted in the older group of patients. Pain was also felt by this group, particularly at the onset and therefore they refused

Fig. 3 (Caffey) Progressive changes in the left tibia and fibula from the third to the fourteenth week after onset. a, Three weeks after onset the medial side of the tibia is covered with a faint, short, thin strip of water density (arrows). b, Five weeks after onset the tibia and fibula are surrounded by long, thick, sclerotic envelopes of calcium density. c, Eight weeks after onset the cortical thickenings have increased in depth and density. The medial surface of the hyperostosis is now rough. d, Fourteen weeks after onset the hyperostoses are shrunken in comparison with earlier findings. The absence of metaphyseal and epiphyseal changes suggestive of scurvy at all stages is noteworthy. There is a striking absence of transverse lines in these last films.

to walk. It is Caffey's opinion that walking and weight bearing may yield traumatic possibilities to the pathogenesis of infantile cortical hyperostoses.

Repeated x-ray examination of the susceptible bones may avert confusing the bone thickening with parotitis neoplasm and osteomyelitis of the mandible. The painful pseudoparalysis of the extremities may be confused with scurvy. Fever, painful extremities, and hyperirritability may be masquerading poliomyelitis. Anemia, fever and bone pain may simulate infantile leukemia, rheumatoid arthritis, and rheumatic fever. The components of the syndrome common to all patients are deep swellings of the soft tissues and cortical hyperostoses in the neighboring bones.

SAMUEL L. GOVERNALE, M.D.

Stack, J. K. and Hunt, W. S.: Radiohumeral Synovitis. *Q. Bull. Northwest. Univ. M. School* 1946 20 394.

The term 'tennis elbow' as used to diagnose pain and disability in the posterolateral aspect of the elbow is incorrect. It fails to differentiate extra- and intra-articular lesions of the radiohumeral joint. Disorders of the radiohumeral joint usually come under observation in from 1 week to 6 years after the onset; they are caused by a trivial injury or by

an unusual exertion. The symptoms are tenderness and pain in the posterolateral aspect of the elbow, and often a grinding sensation on pronation and supination of the forearm. Very often there is radiation of pain along the extensor surface of the forearm. There is weakness in the grip to the extent that the patients inadvertently drop objects and many patients are unable to perform the finer movements of the hand i.e. buttoning of the collar button, knitting etc.

Examination usually reveals tenderness over the posterolateral aspect of the elbow. The patient is able to lift heavy objects when the forearm is kept in supination but is unable to perform the same task if the arm is pronated. Often a grating sensation is palpable or even audible in the area of the radiohumeral joint on pronation and supination of the forearm. Rarely a slight fullness is found over the lateral aspect of the radiohumeral joint.

There are several pathological entities which may be responsible for these symptoms. The most common lesion is an incomplete tear of the origin of the common extensor muscles, associated with underlying periostitis. Sometimes the periostitis reaches proportions to be discovered only on x-ray examination and it is then diagnosed as epicondylitis ('epicondylalgia' by the older writers).

The existence of a radiohumeral bursa is questioned by many workers. Some authors have found bursitis to be the etiologic factor in these conditions (as demonstrated in dissected cadavers). In some cases a pea-sized mass of granular, areolar tissue and fat is found to lie deep in the conjoined tendon and externally but exactly over the capsule of the radiohumeral joint. Curetting away of this so-called bursal mass relieves the symptoms.

The intra-articular lesion might be caused by repeated pinching of the redundant synovial membrane followed by hyperemia and subsequent thickening and villous formation. Another intra-articular lesion may be caused by fraying of the orbicular ligament or the coronary ligament.

Most of the complaints will clear up without treatment of any kind if the particular movement causing the pain is avoided. One author reported that the condition may exist for a period of 30 years.

Conservative treatment consisting of sling immobilization heat in the form of packs or diathermy or plaster immobilization is recommended. The majority of patients will get well. Patients who do not recover after a reasonable period of time are suspected of having intra-articular lesions, and surgery is recommended. The surgical incision is the same as that used for the approach to the head of the radius. The radiohumeral joint is incised and the offending tissue is removed. Four patients in whom conservative treatment failed were operated on by the author.

GEORGE L. REINA, M.D.

Sutro, C. J.: Para Articular Ossification of the Soft Parts of the Ankle; Complication of the Sprain with or without Fracture of the Shaft of the Ipsilateral Fibula. *Arch. Surg.* 1946, 53, 44.

A thin plaque of increased density in the region of the inferior transverse or posterior ligaments of the ankle was noted in 3 of 45 sprained ankles reported in this article. The 3 patients had unusually long convalescences, suffering recurrent pain and swelling for the duration of the follow up period (4 to 7 months) while the other 42 patients recovered in from 4 to 6 weeks. In 3 other patients who sought treatment for recurrent pain and swelling of an ankle which had been sprained 2 to 3 years previously similar densities were noted in the roentgenograms. The densities were also noted in 2 patients who had sustained fractures of the shaft of the fibula as well as a sprain of the ankle and in whom the recovery from the sprain was prolonged and more troublesome than the fracture.

The author believes that the density is due to ossification and not calcification of the connective tissue. The bone is not new periosteal bone. The basis for the recurrent swelling of the ankle may be due to inflammation or irritation of the synovial surfaces by the ossification of the para-articular tissues.

The treatment given all the patients with this complication of ankle sprain consisted of assignment to duties not requiring excessive walking, the application of elastic supports to the ankle and repeated

courses of hydrotherapy. This resulted in partial resolution of the swelling and pain, but did not cause the disappearance of the densities in the soft parts. No surgical correction was attempted.

The author believes that this condition is secondary to the ossification of the tibial collateral ligament of the knee.

NEWTON C. MILES, M.D.

Agati, D.: Circumscribed Osteochondritis of the Astragalus (Osteochondral dissecans of the astragalus). *Riv. Med.*, Milano, 1946, 33, 102.

The author cites 2 personal cases of osteochondritis dissecans (circumscribed osteochondritis) of the astragalus and 13 other cases found in the literature.

He finds that males and persons in the young age group from 20 to 30 years, are afflicted more often than females and those of other ages, and that in older groups arthritic characteristics may mask the initial osteochondritic focus. He finds that there is also a preferential site for the lesion in the astragalus just as there is in the knee where the tibia and hip and that this is usually the medial side of the trochlea of the astragalus (11 cases of 13). As in the other locations he feels that the cause is due to predisposing anatomic and functional factors and conditions of trophic unsteadiness from a vascular deficit. In the astragalus the greater weight comes to bear heavily on the trochlea of the tibia and is important factor.

Agati found that in the majority of cases the occupational trauma which determined a recurrence of the syndrome and which consequently brought the patient to roentgenological examination was of minor importance, and that the disturbance even though slight antedated the trauma. The trauma, therefore, more than the direct causal agent of the disease seems to be the aggravating factor and the revealer of a latent pathological state. Therefore, he believes that there can be silent lesions of osteochondritis that are never diagnosed.

From the clinical point of view he notes that the lesion has a variable course—it is possible for it to end in a spontaneous and complete cure or maintain itself unmodified for months or years. The subjective symptoms are usually limited to moderate local pain which is often interpreted as dependent on arthritic factors or ascertained roentgenologically in other cases. The swelling is not constant and appears usually after the revealing trauma of the disease—usually in part or all around the ankle so that one suspects a sprain or tries to exclude a fracture.

The x-ray findings are comparable to those observed in other articular sites. The author describes these findings and cites an example in which the osteochondritic mass seemed to be mobilized free in the joint but at operation was found not to be free therefore he gives a warning regarding operative interference.

Regarding therapy he offers a word of caution—keeping all the evidence in mind. Therapy may be surgical when locking phenomenon or limitation of

joint movement are found—one must be certain of the existence of an endoarterial mobile mass. Therapy may be conservative (rest immobilization physical therapy) when a joint mouse cannot be recognized even after pneumarthrography. Regarding the astragalus there has not been observed its mobilization of the isolated piece therefore the conservative method is the best treatment.

The author describes the roentgenological differential diagnosis and concludes by saying that up to now osteochondritic lesions of the astragalus have been found on the trochlea.

G ALBIN LIVA, M D

SURGERY OF THE BONES, JOINTS
MUSCLES, TENDONS, ETC

Morris, H. D.: Tenon and Mortise Grafts for Bridging Metacarpal Defects Due to Gunshot Wounds. *Surgery* 1946 20 364.

A method for bridging defects in the metacarpal bones due to gunshot injuries is presented. The method is applicable when damage to the nerves and tendons is minimal and when loss of substance and continuity of the bone results in deformity and disability.

The procedure is to resect the distal and proximal fragments until a transverse cortical surface can be obtained. The fragments are then reamed out and a cortical tibial bone graft of sufficient length and a tendon 1.5 cm. long on either end is then used to bridge the gap. The graft can be more easily placed if a slot is cut in the distal fragment and the tendon held in place with a wire loop. If necessary the graft may be seated into one of the distal carpal bones. Immobilization is maintained for 8 weeks after which time union will be complete.

VENKOW C. TURNER, M D

Tavernier, L.: The Treatment of Chronic Congenital Dislocation of the Hip (Le traitement des luxations congénitales invétérées de la hanche). *Rev orthop* Par., 1946, 31 109.

A considerable number of congenital dislocations of the hip still fail to get orthopedic treatment in so many. The majority of these patients come to the orthopedic surgeon at a time when arthritis of the hip has made their condition intolerable.

Many surgeons have developed a definite technique in the treatment of these conditions and adhere to it. Most French surgeons are satisfied with palliative surgery i.e. subtrochanteric osteotomy. Other surgeons perform reconstruction operations. The author adapts the procedure to each individual case.

The author has done most of the operations recommended during the last 20 years. In the last few years an "enervation" operation of the hip joint was done associated with other procedures or alone in cases in which pain and not lameness was the outstanding complaint. On consolidation of the experiences thus gained a certain procedure was developed

which proved to be very satisfactory in the treatment of congenital dislocation of the hip and the following operations were completely abandoned: resection of the femoral head, arthrodesis of the hip and the operation of Zahradnick. The following operative procedures: reconstructive arthroplasty, "shelf" operations, subtrochanteric osteotomy and enervation of the hip deserve further discussion.

Nové Jossérand has resected the femoral head in old patients who had intolerable pain. The author did this procedure once and found that it relieved the pain a great deal but resulted in a very unstable hip in fact the hip was much worse than prior to the operation. This procedure should be done only in cases in which there is a decalcified head which has resisted all attempts at reduction. A secondary stabilizing operation is necessary i.e. a shelf operation or subtrochanteric osteotomy. In this group only 1 arthrodesis of the hip was done in an old patient who had an old painful unilateral dislocation with good result. There were unusual circumstances in this case because ordinarily one tries to obtain a better result than a fused hip. However this operation should be kept in mind as a reliable procedure which can be used if other procedures fail.

The Zahradnick operation (open reduction, shelf operation and shortening of the femur) was done in a few patients. With the exception of a few good results most of them were unsatisfactory and after a patient died due to shock at operation this procedure was completely abandoned.

Arthroplastic operations of the hip joint are sound but have the disadvantage of being difficult and major operations. The difficulty lies in the reduction of a fixed head due to periparticular adhesions and in maintenance of the reduction once it has been accomplished. This operation was done in 14 cases. It consists in forceful traction of the leg with the use of the Kirschner wire 2 weeks prior to the operation, freeing of the upper end of the femur at the operation, too resection of the capsule, reshaping of the femoral head to fit the new acetabulum above the old one at a level where the head can be reduced and maintained comfortably and interposition of fascia lata. The result was very good in 3 cases. The hip was stable and motion was satisfactory. The shortening was negligible. In 7 cases the result was good. There was a solid hip with diminished motion. One of these cases terminated in an ankylosis with good function. One patient had an excellent joint post-operatively as far as stability and flexibility were concerned but there was considerable pain. A second enervation operation on the hip joint alleviated the pain completely. Two patients had fair results. The hip was solid and not painful but there was a considerable limp. Two patients had poor results. The hips became dislocated as soon as they were taken out of plaster and reoperation was necessary. Subtrochanteric osteotomy was done in both cases in 1 muscular atrophy remained considerable in spite of a flexible hip joint and the patient's activity was restricted to walking in his home with canes.

Generally these results can be classified as satisfactory as far as redislocation is concerned but they are disappointing as far as muscular atrophy is concerned. Even in the results classified as good weakness of the gluteal muscles persisted which caused the patient to limp and to have a tired feeling after walking. It was interesting to find that patients with an ankylosed hip were more satisfied than the ones who underwent arthroplasty and that they walked and danced without a limp. It is the danger of insufficient muscles which makes it difficult to recommend the arthroplasty more often.

It is much more difficult to draw definite conclusions as to the value of shelf operations. This procedure has been the main operation for old dislocation of the hip for the past 20 years. Although no one else uses shelf operations in high posterior dislocation of the hip the author has used it in cases of this type with good results. The classical indication for the shelf operation is the locked anterior dislocation and subluxations which are very rare. In these cases the operation offers a mechanically sound solution and forms a solid roof over the "locked femoral head." In supra-acetabular dislocation, however satisfactory stability is present as a rule and there is only a negligible amount of lameness. It is pain that sends the patient to the orthopedic surgeon. The pain is similar to pain in deforming arthritis and does not resemble pain due to ligamentous strain observed in young patients.

The supra-acetabular dislocations are well tolerated until puberty at which time pain appears after prolonged walking and disappears after moderate rest. There is no limitation of motion except the limitation caused by pain due to ligamentous strain. In these cases a shelf operation is very successful as the pain and limp disappear. The postoperative course might be complicated by a peculiar arthritis which is transient and does not impair the final good result. It is very unusual for arthritis to occur if the shelf is constructed at a level which does not require the head to be lowered too far. One is justified in assuming that deformity and deforming arthritis will not occur in cases in which the head lies under a shelf under nearly normal mechanical conditions but would occur if not treated. On the other hand, if a patient with a supra-acetabular dislocation has reached the age of 35 or more without any serious complaints and then develops pain while at rest, limitation of movement and abnormal posture shelf operation is not the rational procedure. In this series shelf operations were done in these cases. Some have helped the patient but only for 1 or 2 years. This is not surprising if one realizes that this operation does not change anything but the mechanical action of the hip. Many patients did not get any benefit at all from the operation and in many the condition was actually worse after the operation. The newly constructed shelf blocked the deformed head limiting its movement even more and thus limiting movement in the hip joint without relieving the pain. One can readily see why the shelf operation is con-

traindicated in these cases and why arthroplasty or "enervation" would be the better operation.

The shelf operation was performed on female patients between 20 and 30 years old with much success. The best results were observed in some cases only after the lapse of 1 or 2 years of persistent pain. This time was necessary to permit the head to adapt itself to the shelf. Before it can be judged that the operative procedure will eventually be successful it is important to study the shape of the head very carefully. In 2 cases there was a sharp angle at the top of the head where it rested against the ilium. This deformity was responsible for a poor result and always is a contraindication to the shelf operation. One readily sees that the shelf operation is limited to old dislocations of the anterior type in patients not older than 30 years.

Subtrochanteric osteotomy is the treatment most frequently used for old dislocation of the hip in France. It is a simple operation. It is done with a double angulation: one in the frontal plane to correct the adduction deformity—by stretching the muscles extending from the pelvis to the trochanter and giving pelvic support—and one in the anteroposterior plane to correct the pelvic tilt and to compensate in advance for the balance of the pelvis and the knee. It is a very good palliative operation which improves stability and abolishes pain in the hip. It is frequently the only operation that can be employed in severe deformities due to high posterior dislocation of the hip. The results, although satisfactory are inconsistent. Sometimes there is considerable increase of movement, sometimes not sufficient relief of the pain in the hip joint.

The results are much more favorable in unilateral dislocations in which a better balance of the pelvis can be achieved by forceful abduction of the femoral fragment which also will minimize the shortening of the leg and in which limitation of motion is not too disabling. Ten operations were done in this series; the results were very good in 8 cases, and fair in 2. In bilateral dislocations the results are less favorable. Better results were obtained in cases in which osteotomy was done on one side and a shelf operation or arthroplasty on the other (15 good results and 3 fair). The results in only 3 cases of bilateral dislocation were classified as good postoperatively. 4 others were classified as poor because of persistent limp, stiffness of the hip, faulty gait, and persistent pain. The results on more recently operated patients confirmed these findings. Pain persisted in 4 of 9 operative patients.

Röntgenograms showing the anatomical result do not explain the persistence of pain. Osteotomies which appear roentgenographically correct often are associated with persistent pain while other osteotomies anatomically less satisfactory, are decidedly very satisfactory. In spite of this rather paradoxical fact, which is true for pain only and definitely does not apply to movement, technique of the procedure is very important. It is important in every case to determine accurately the location of the osteotomy

and the angle in the frontal and anteroposterior planes. The Mommson technique is the best from this point of view. The projecting portion of the upper fragment maintains the position securely at a chosen degree of angulation until the wound is closed and the plaster is applied. In the determination of the angle of abduction in the frontal plane one should consider that a wider angle gives a better result since it helps to maintain the balance of the pelvis. This, of course is possible only in unilateral dislocation of the hip. In bilateral dislocation two operations are performed, the second after a sufficiently spaced interval following the first operation. It is surprising to notice how satisfactory the result is following the first procedure and how little benefit is derived from the second operation.

From the orthopedic point of view enervation is entirely inadequate. The fact however, that patients consult the surgeon late because of pain and only secondarily because of lameness made the author treat these patients by enervation. This operation was done on 19 patients. At the same time 15 patients who had bony operations were observed for the same period of time as control cases.

The history of these 19 patients was surprisingly similar. They were able to get along fairly well for a number of years the lameness not being extensive in fact, they were able to walk more than 10 kilometers daily. One day pain occurred first after long walks then after shorter ones, and finally there was pain even at rest and especially at night. At the same time limitation of motion in the hip made itself noticeable there was abnormal posture and at the end of 2 or 3 years the patient became disabled. These complications usually appeared between the ages of 30 and 35. In a small group of individuals, deforming arthritis appeared sooner at the age of 25 or later at the age of 45. In most of them the enervation operation was followed by absence of pain. Faulty posture due to contractures or spasm of the muscles disappeared motion was improved and the patients were again able to walk as far as they could prior to the occurrence of pain. In 9 cases very good results were obtained in 8 the results were fair and in 2 there was no improvement. The 9 results were classified as very good because the pain and lameness had completely disappeared and the ability to walk had greatly improved. The patients with fair results had less pain, the pain occurred after long walks, or the pain had stopped in certain regions and occurred in others. The last case in this group was one of the first operated on and only the branches of the obturator nerve were cut. Some pain persisted but finally stopped after section of the posterior branches of the sciatic nerve.

Section of the obturator branches alone was done in the first 7 patients operated upon with good results in 1 case fair results in 6 cases and pain persisted in the posterior regions in 3 cases. These patients were advised to have the operation completed by having the nerve to the quadratus femoris muscle sectioned. The last 12 patients were subjected to

total enervation. Eight patients had a very good result, 2 a fair result, and 2 had poor results. In comparing the older with the more recent cases one readily sees the advantage of total enervation over simple obturator enervation.

The 2 failures following the enervation operation in chronic congenital dislocation were just as puzzling as the failures of the enervation operation in deforming arthritis which occur much more frequently. Five patients in the series had bilateral dislocations and were subjected to bilateral enervation operations. There was a total of 24 operations with 2 failures, or 8 per cent. In these 2 failures the pain seemed at first to have stopped only to recur in one case after a few weeks and in the other after 7 months. Since total enervation was done the once suggested theory of an abnormal articular branch is eliminated but the reason why this operation failed in 2 cases is not explained.

The control group of 15 patients observed during the same period of time had osseous and articular operations only. Three patients in this group underwent an enervation operation with good results in 2 and improvement in the condition in 1 patient.

The favorable results indicate how valuable the enervation operation is in the treatment of chronic congenital dislocation of the hip either alone or in association with any other basic operation on the hip.

There are 3 main considerations in determining the indication for one of the many types of operations in congenital dislocation of the hip: the type of the dislocation whether there is unilateral or bilateral dislocation and the age of the patient. In young patients after puberty and until from 25 to 30 years of age the following reconstructive operations are indicated—the shelf operation for anterior dislocation and arthroplasty for the posterior form. In these cases the indication is precise since function is the most important factor. Sometimes these young patients tolerate the dislocation well and are without appreciable lameness yet they desire to know what can be done for them. The answer is that operation at this time might prevent complications at a later time or the operation might not be of any benefit at all. If there is a supra-acetabular dislocation it is always better to do a shelf operation because it is less unlikely to fail than an arthroplasty. In case of unilateral dislocation an arthroplasty should be tried if the patient desires it, because if stiffness occurs, an arthrodesis can be done secondarily without handicapping the patient too much. In bilateral dislocation a shelf operation is done on the lower hip and if the operation is successful an arthroplasty is attempted on the other side. The decision is much more difficult in cases of posterior dislocation of the hip.

In cases of high posterior dislocation which cannot be lowered by heavy skeletal traction sufficiently to allow arthroplasty, the subtrochanteric osteotomy will give good results in unilateral cases. The bilateral dislocations require further considerations if one side responds to traction better than the other an arthroplasty can be done if an osteotomy is done on

the other side. If both sides are high the lordosis is severe and adduction deformity is considerable, a bilateral osteotomy should be done. If pain is the main complaint and the patient is prepared to accept the lameness, the enervation operation is indicated even in the young patient.

In the older patient these conditions present themselves in an entirely different light. If he seeks advice in a late stage he usually has no severe lameness but the pain in the hip has become intolerable. The enervation operation has all the advantages of a simple operation with the possibility of abolishing pain and putting the patient back to a stage before the pain had limited his gait and posture and before the appearance of the deforming arthritis.

The enervation operation is for the time being a valuable, palliative efficacious, and minor procedure in the treatment of chronic congenital dislocation of the hip either alone or in combination with other osseous procedures.

GROVER I. RICE, M.D.

FRACTURES AND DISLOCATIONS

Speed, E.: Subtrochanteric Osteotomy for Ununited Fracture of the Neck of the Femur. *Ann Surg* 1946, 24 576.

The author reviews briefly the mechanics the pathologic changes, the technique after treatment and results of subtrochanteric osteotomy. Before determining the advisability of subtrochanteric osteotomy the following requirements must be met:

1. All tractions or splints and fixations (including internal fixation) must be removed.

2. Open ulcers, or decubitus ulcers near the fracture area must be healed.

3. Roentgenological examination of both hips in a posteroanterior plane and a lateral view of the fractured hip must be obtained to determine (a) the amount of absorption of the neck, (b) the presence or absence of infection or sequestra or ankylosed joint (c) the rotation of the head fragment, and (d) the viability of the head as determined by its relative density.

If these factors are unfavorable, and if the head of the femur is completely necrotic, one of several reconstruction operations on the hip may be the best procedure especially in patients under 60 years of age. If these conditions are found to be favorable the patient's general condition (unless obviously moribund) his fear of follow-up care his age and even his weight may be discounted.

Preliminary traction on the leg by means of a sturdy steel pin inserted through the calcaneus may be helpful in marked overriding of the fractured neck. At operation manipulation on a fracture table is performed to put the fragments of the ununited neck in apposition and to hold them thus with slight abduction of the legs. The reduction at the neck of the femur is checked by roentgenograms in two axes.

Following operation a plaster-of-Paris cast is applied. Eight weeks of immobilization suffices for union.

Of 10 patients operated upon, whose ages ranged from 63 to 72 years, 1 fatality is reported.

ORTHOPEDICS IN GENERAL

Coppo, M., and Calamaro, S.: The Effect of Innervation on the Mineral Composition of Bone. New Experimental Research (Sull'azione dell'innervazione sulla composizione minerale delle ossa. Nuove ricerche sperimentali). *Sperimentale*, 1947 96 503.

Coppo has for some time been studying the factors that bring about mobilization of the minerals in the bones so that they are available for use elsewhere in the body. Leriche and Policard asserted that decalcification of bone is dependent on a disturbance of the normal relationship between the composition of the blood, the activity of the circulation, the condition of the connective tissue determined by the internal secretion, and the mechanical effects of pressure. They leave entirely out of account any effect of innervation on the composition of bone, although a considerable amount of research has been done pertaining to such an effect. The question is not entirely settled however and there are still authorities who deny it. The various conclusions of a number of authorities are given.

For the purpose of further study of this factor the authors operated on 20 rabbits, removing a section of the sciatic nerve near its origin, and in some cases also a section of the cranial nerve. The animals were divided into two groups of 10 each, those of one group being killed from 11 to 21 days after the operation and the others from 24 to 75 days after it. The normal composition of the mineral ash of the bones was determined and compared with that of the animals in the two groups. Tables are given showing the details of the results and the comparative content of ash, calcium, and phosphorus in the groups. The determinations were made on the tibia of the denervated side. It was found that in the group killed after from 11 to 21 days there was a marked decrease in ash, calcium, and phosphorus, but this decrease had been compensated for in the animals killed after from 24 to 75 days.

These experiments show conclusively that innervation has an effect on the mineral composition of bone, but there are some points still unexplained, such as the great variation in the amount of decrease of the minerals in the animals of the first group and the reasons for the compensation in the second group.

AUGUST G. MORAN, M.D.

Sorrel, E., and Longuet, Y. J.: The Anterior Transbrachial Route in Surgical Repair of Supracondylar Fractures of the Humerus in Children (La voie transbrachiale antérieure dans le traitement des fractures supra-condyliennes de l'humerus chez l'enfant). *Rev arth* Par 945, 31 7.

By the term anterior transbrachial route is meant a surgical approach to the inferior extremity

of the humerus which extends across the brachialis muscle, this muscle having usually been cut transversally at the time of a supracondylar fracture of the humerus.

It seems paradoxical to repair a fracture of the elbow by the anterior transbrachial approach. The elbow is covered anteriorly by the thickest portion of the brachialis and biceps muscles and the radial and median nerves as well as the humeral artery and veins pass in the same area from the upper arm into the forearm.

The posterior approach with sectioning of the olecranon is excellent in adults. In children, however it is of questionable value. A number of workers state that usually severe stiffness and, in some cases ankylosis of the elbow joint follow. The soft tissues anterior to the elbow joint are frequently lacerated by the anteriorly projecting fragment of the diaphysis. If the posterior soft tissues are cut a considerable amount of trauma is added. Furthermore the posterior portion of the periosteum is cut which eliminates an important barrier protecting the soft tissues from the formation of osteitis ossificans. There is also the danger of injury to the epiphysis. When the posterior approach is used the small periarticular vessels are cut. This loss of collateral circulation is liable to have serious sequelae if because of pressure of the diaphyseal fragment the humeral artery becomes thrombosed.

The posterolateral approach is to be preferred and is superior to the posterior route. The object is not to go through the supinator muscle which gives little exposure and is liable to cause partial paralysis of the radial nerve. The incision is carried posteriorly to the supinator which is detached from its insertion along the lateral aspect of the humerus. Leveuf and Godard state that this approach is the best for open reduction of supracondylar fractures in children. There are two reasons why the authors discarded this approach: (a) the muscular dissection is considerable, which leads to the formation of osteitis ossificans, and (b) it does not expose sufficiently the injured structures which lie anteriorly to the elbow joint which makes repair of these structures nearly impossible.

Most supracondylar fractures can be reduced by the closed method. There are three principal reasons which make open reduction a necessity in these cases: (1) failure of the closed method of reduction (2) in injuries to the artery, veins, and nerves and (3) compound supracondylar fractures.

The usual position of the diaphyseal fragment is familiar to most orthopedic surgeons. The fragment is displaced anteriorly, has a sharp irregular fork-shaped edge, and usually has two sharp projections on its lateral and medial borders. The fragment usually lacerates the muscles and extends to, and sometimes pierces the skin.

In a small number of cases the skin is perforated by the diaphyseal fragment. The site of the perforation is nearly always the same: the anterior aspect of the elbow just superior to the crease. Compound

fracture in itself constitutes an indication for surgical treatment. Muscular interposition nearly always explains the failure of closed reduction. The anterior muscle group in most cases is pierced by the distal end of the diaphyseal fragment. The lateral and medial edges have diverging edges which causes them to pierce the muscular tissue. In these cases manual reduction even with the help of Kirschner wire traction is futile. The upper fragment impinges also on the vessels and the nerves which pass in front of the elbow joint. These structures are compressed between the end of the upper fragment and the coronoid process. The compression usually causes paralysis of the nerves and obstruction of the humeral vessels with subsequent Volkmann's contracture. The first signs of impending danger are diminished radial pulse, swelling, cyanosis or discoloration of the hand and diminished function of the fingers.

If reduction is accomplished within the first hours after the accident most of the complications due to the compression of the nerves and vessels can be averted. A general anesthetic, traction by Kirschner wire and x ray control are necessary for closed reduction of a severe supracondylar fracture of the humerus. If 24 to 48 hours have passed before reduction can be accomplished the changes caused by the damaged nerves and vessels usually are permanent. There is no agreement as to whether or not open reduction always is necessary in these cases. Boehler states that closed reduction is the treatment of choice and open reduction is not indicated at the beginning of the treatment. Others think that immediate open reduction is absolutely necessary. It is the authors' policy to do an open reduction if there are vascular injuries. In case of nerve injury no immediate operative intervention is necessary because neurolysis or delayed nerve suture gives satisfactory results. If the postreduction roentgenograms are unsatisfactory, open reduction is indicated in every case. In case of injury to both nerves and vessels immediate surgical intervention is necessary.

Since 1936 the authors have been trying to find a way to reduce the fracture and to repair the injured vessels and nerves through one and the same incision. The anterior transbrachial approach was worked out and used since that time in about 10 cases. The study of these cases has enabled the authors to form an opinion as to the proper indications, contraindications and technique of this approach.

There are four indications for the anterior transbrachial approach: (1) supracondylar fractures of the humerus (articular fractures i.e., intercondylar and transcondylar fractures are excluded because this particular approach does not furnish adequate exposure) (2) supracondylar fractures of the "extension" type only in which the upper fragment lies in front of the elbow joint (3) cases in which the anterior displacement of the diaphyseal fragment is considerable and (4) recent fractures only. In old cases one could use this approach to do an arteriectomy, sympathectomy, neurolysis or nerve suture. One must not use this approach however to excise

usually with a rapid onset of paralysis, any form of therapy is useless.

Included in the present article is a discussion on the neurological complications of spinal tuberculosis. The surgical management of spinal tuberculosis at different levels is discussed.

Spontaneous atlantoaxial subluxation is illustrated by the report of a case history. The treatment consisted of Blackburn skull traction with a pull of 9 to 13 pounds while the patient lay in a posterior plaster shell. Within a period of 10 days, reduction was complete and an occipitatlantoaxial fusion was accomplished with a split rib graft.

Two 4½ year old girls with cervicothoracic Pott's disease came under observation. Both patients were treated with skull traction and a posterior and anterior shell. A special device to prevent drop foot is described in detail.

Conservative treatment is recommended routinely for thoracic Pott's disease. In cases in which neurological deterioration continues in spite of adequate immobilization the anterior decompression procedure, as described by Mr. Dott, is employed. This procedure was used in a group of 13 patients between the ages of 6 and 65 years. Through a curved skin incision from midline to midline of the back the trapezius and latissimus dorsi muscles are reflected laterally and the longitudinal posterior muscles medially. Three or more ribs are then resected. The intercostal nerves are followed to locate pedicles and the dura. The pedicles are then removed to expose the anteriorly located abscesses. The diseased vertebrae are excavated to eliminate any pressure on the thecal layers. The abscess is evacuated and sequestra and displaced intervertebral discs when found are removed. At the termination of the operation normal pulsation of the dural sac and relaxation of the intercostal nerves are noticed. A gibbus usually facilitates exposure of the diseased area considerably. Skull traction is applied as a preliminary step and the operation is done in an anterior plaster shell.

In every one of the 13 patients operated on, a mechanical factor was responsible for compression of the spinal cord.

It is important to realize that normal spinal fluid manometer readings and a low protein content do not necessarily rule out compression of the cord.

Three of the 13 patients died—2 of uremia in 4 to 5 days after the operation and 1 patient from an unrelieved compression of the cord. There was no evidence of dissemination of infection following operation.

In the closing remarks of the authors, 2 cases are briefly cited. In one case stereoscopic views of an apparently quiescent juvenile kyphosis revealed calcification of a paravertebral abscess. In the other case that of a 9 year old patient a secondary focus (tuberculoma) was discovered in the cerebellum. Finally it is pointed out that symptoms simulating ruptured intervertebral disc may very well be due to a tuberculous process in the same area.

GEORGE I. REIN, M.D.

Cleveland, M.: Orthopedic Surgery in the European Theater of Operations. *Ann. Surg.* 1946, 124: 188.

The writer assumed the duties of Senior Consultant in Orthopedic Surgery in the European Theater about 3 weeks before D Day following a year's duty at the Station Hospital at Fort Jackson and 9 months duty as Orthopedic Consultant for the Fourth Service Command.

The earlier battle casualties with compound fractures and amputations were observed and it was apparent to all the surgeons that there was room for improvement in the care of battle casualties with wounds involving the bones and joints.

Prior to D Day the increasing personnel of the Army in the United Kingdom and the Air Force sustained many injuries of varying severity. During the period of Army training the Medical Corps had its training program. The Chief Surgeon and his staff issued a Manual of Therapy for the ETO in May of 1944. This was supplemented from time to time by circular letters as experience was gained.

The earliest hospitals to arrive in the Theater were well staffed, each one of them having from 8 to 50 officers trained in bone and joint surgery. There were eventually 160 hospitals with the trained personnel spread thinly among them. The amazing fact remains that so much creditable surgery was done with so little relatively well trained personnel.

An interesting and significant study was made among Air Force casualties. Three parallel groups of wounds were treated as follows: (1) by adequate débridement and immediate primary closure; (2) by adequate débridement, immediate primary closure and the use of sulfonamides; and (3) by adequate débridement, immediate primary closure, and the use of penicillin. There was no essential difference in the healing in these three groups, which indicated that surgical treatment was of paramount importance. However the immediate primary closure of wounds in Air Force personnel would have been jolly if attempted on infantrymen wounded under different conditions.

The fixed hospitals, from the standpoint of the orthopedic surgeon, offered greater opportunity for long time contact with bone and joint casualties than did service in the continental hospitals which evacuated compound fractures and amputees at the earliest possible moment. Air evacuation was started within the first week of the invasion and finally the great bulk of the patients were transported by the means.

The first aid care of the wounded with bone and joint casualties rested with the medical enlisted men. Compound fractures of the femur, tibia, and fibula were immediately placed in a half-ring Thomas splint. For compound fractures of the foot and ankle the well padded wire ladder splint was used. Upper extremity compound fractures were placed in slings or swaths.

At the battalion level, plasma was available and whole blood was administered at the clearing station.

The bone and joint casualties for the most part were considered transportable and were sent to evacuation hospitals where adequate and thorough débridement of damaged and necrotic muscle, fascia, and skin was carried out. All possible skin and all bone fragments were preserved. These compound fractures were dressed with fine-mesh plain gauze laid over or into the wound "Packing" with vaselined gauze prevents drainage of blood and exudate, and invites infection. Penicillin was administered and circular plaster of Paris splints of varying types for each of the long bones involved were applied. All of these circular splints must be split to the skin and slightly spread to allow for swelling in transit.

Definitive surgical treatment began at the fixed hospitals in the Zone of Communications. Delayed primary closure of these wounds was the outstanding improvement in the care of these casualties. Delayed primary closure was attempted in 2,393 patients by suture in 2,087 by skin graft in 236 and by combination of suture and skin graft in 70. Skin grafting was done by means of split-thickness free grafts and by pedicled grafts when loss of bone and soft tissue was considerable. Ninety three per cent of the patients upon whom closures were attempted left the hospitals with their wounds healed. Delayed primary closure of these compound fractures can be successfully accomplished in almost 3 of 4 cases which sharply reduces the incidence of osteomyelitis. Long bone fractures were treated with skeletal traction usually with Kirschner wire. Of 3,700 compound fractures, 68.6 per cent were satisfactorily united, 13.3 per cent were united in malposition and 18 per cent were ununited.

The only amputation allowed in the Theater was of the circular type which is considered so emergency measure only and received later revision at the Amputation Center.

The wounded hand was considered chiefly from the standpoint of its soft parts. A pressure dressing with the hand and fingers in functional position was recommended with elevation of the part and early closure of the wound by suture or skin graft.

The proper treatment of wounds involving joints was based on sound surgical principles and a high percentage of joint wounds were salvaged with useful motion.

The divided or potentially divided major peripheral nerve should be given precedence over the compound fracture. Patients with this condition were transferred immediately to a neurosurgical center where the wound was closed by delayed primary suture or skin graft. The fracture being placed in balanced suspension. Three weeks after wound healing the nerve was explored and sutured if found divided. If it was necessary in order to get the nerve ends together the bone was shortened up to 2.5 cm.

The writer concludes his report with a comparison of the medical care of the wounded in World War I with that in World War II. The general level of care of bone and joint casualties was vastly improved there was a more complete and general understanding of resuscitation, evacuation was more rapidly accomplished, overseas hospitals were better equipped and the incidence of infection was lower because of better surgery in the forward areas or the use of sulfonamides and penicillin.

RUDOLPH S. REICH, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Magendie, J. and Tinguand, R.: Pseudembolic Phlebitis—Grégoire's Blue Phlebitis (Phlébite à forme pseudembolique—phlébite bleue de Grégoire) *Bordeaux chl* 1945 3 and 4

Following a brief review of the literature on the interrelations between arterial and venous inflammations, the authors present in detail a case of the peculiar condition known as blue phlebitis, or pseudembolic phlebitis, first described by Grégoire in 1938. The patient was a woman of 36 years with hepatic disease and a complicating pyosalpinx on the left side. The pus contained numerous aerobic and anaerobic organisms and had extended from the pelvis into the iliac fossa and left lumboilic region passing through the iliac veins. The patient was suddenly seized with a violent pain in the calf of her left leg with marked changes in her general condition. Simultaneously she developed edema, cyanosis, chilling and complete disappearance of the femoral pulsations on the same side with slight diminution of the oscillations on the opposite side. Following infiltration of the sympathetic nerve the pulsations reappeared for a few minutes but then disappeared again. The patient collapsed and died.

Autopsy revealed a flat empty artery, with slight periarteritis but no endarteritis. The phlebotic veins were distended by a jellylike friable blood clot.

Seventeen similar cases from the literature are tabulated with data concerning the functional signs at the onset of the condition, physical signs, arterial signs, condition of the opposite side, the end result and verification of the vein and artery.

Grégoire's blue phlebitis or pseudembolic phlebitis is characterized by a violent sudden onset including severe pain and circulatory collapse. The chief symptoms are cyanosis, edema, chilling and hypesthesia, and abolition of the arterial pulsations. The two functional signs at the onset are common arterial and venous manifestations. The severe pain and collapse may be caused by sudden arterial obliteration or massive and rapid venous thrombosis. Attention has been drawn repeatedly to the possibility of error in diagnosis between blue phlebitis and arterial embolism of the extremities.

Among the physical signs, only one is of venous origin, namely the edema. Two are of manifest arterial origin, namely the chilling with hypesthesia and the abolition of the pulsations. The fourth symptom, cyanosis or acrocyanosis, was considered up to the time of Grégoire to be of venous origin, but he attributed it to arterial causes, and later findings have confirmed his theory.

The initial pain is usually violent and sudden. It is generally located in the calf of the leg, sometimes involving the whole limb to the root of the thigh in the groin.

In rare cases there is no pain as, for instance, in Bergeret's case, in which the syndrome appeared progressively in a greatly debilitated patient. In Grégoire's case there was a simple swelling and a sensation of heaviness. These exceptions only help to prove the rule of sudden extremely painful onset.

A change in the general condition with circulatory collapse is mentioned in the majority of reports. Some patients have pale faces with anxiety, a sensation of impending death and a small rapid pulse. This picture may be related to the extent of the thrombosis. The phenomenon of intravenous coagulation probably occurs suddenly with the brutality of a physicochemical reaction. The sudden obstruction leads to coagulation of the blood with resulting cardiac collapse, as brutal as in massive pulmonary embolism. In the present case the veins at the root of the lower extremity were distended with blood of the consistency of current jelly and homogeneous throughout the entire region of the leg and pelvis. These cases of massive coagulation evidently carry a desperate prognosis, for although certain drugs may prevent coagulation once it has begun no means of checking it is known.

The dramatic onset may be due to generalized spasm, having its point of departure in a relatively minimal thrombosis, the resolution of which may result in instant relief. It is unwise, therefore, to base the prognosis on the intensity and apparent severity of the initial violent circulatory collapse. In many cases the absence of pulsation is due to spasm without thrombosis as evidenced by recovery even though temporary following intervention on the sympathetic system. The cause of the spasm may persist in spite of the treatment. The maximum reflex action probably springs from the perivascular sympathetic nerve irritated by the sudden distention and inflammation of the venous walls in cases of massive thrombosis. One may thus, have to deal with a functional reflex, a sort of autodefense. Sudden distention of the venous system diminishes the supply of blood to the arteries. The enormous, fusiform, moniliform dilatation of the vein, and marked perivascular inflammation encountered at operation, and seen at autopsy indicate the intensity of this spasmodic reflex. In cases involving a whole limb it would be most difficult to cut the path of the vasomotor reflex. Here an operation as high as possible on the sympathetic nerve would be indicated, but it seems problematic whether the state of collapse in such patients would permit resection of the lumbar sympathetic. The authors were greatly deceived by the transitory effect of infiltration of the lumbar sympathetic in the present case.

The prognosis in blue phlebitis is poor even though the spasmodic element is indicated by intermittent arterial obliteration. Some cases go on to complete recovery while others go on to an ordinary

phlebitis with final cure. However the outcome is unfavorable in the majority of cases. Many cases will require amputation for gangrene and numerous fatal cases have been reported.

Besides this blue phlebitis due to arterial spasm complicating a phlebitis, of which the present case is an example there is phlebitis of similar aspect due to the more common association of arteritis and chronic phlebitis. In this case the symptoms are progressive and the striking initial functional or general symptoms are lacking. Although this type of phlebitis is a blue phlebitis it cannot be classified as a pseudembolic phlebitis and its diagnosis is of much less significance. Between these two types, the pure spasmodic and chronic organic arteritis, all transitions are possible with the association of a spasmodic element and a more or less marked endarteritic lesion. Nevertheless the pseudembolic type due to spasm remains the most curious and interesting of these arteriovenous inter reactions.

Shumacker H B., Jr. Incisions in Surgery of Aneurysms. *Ann. Surg.* 1946 124 586

In the surgical treatment of aneurysms it is important to use an incision which permits of easy and complete access to the vessels involved. The incision should be so placed that, by lengthening it the vessels distal and proximal to the site of suspected pathology are accessible without difficulty.

The author describes this general problem and particularly that of exploration in the popliteal fossa and in the antecubital space. In his experience it is rarely if ever necessary to use incisions other than those which are sound from a plastic standpoint. A number of specific problems are discussed and methods which have proved satisfactory are described.

Fig. 3. Incisions used in exposure of brachial vessels in antecubital fossa. a, Usual incision for exposure of brachial vessels in antecubital space. b, Incision used when lesion is suspected in proximal portion of ulnar vessels. c, Incision used when brachial vessels are involved just proximal to antecubital crease. d, Incision used for exploration of distal end of brachial or proximal end of radial vessels. terized by a tendency to bleed in the presence of normal platelets a normal coagulation time and an increased bleeding time. The recognition of a typical case of pseudohemophilia is not difficult. Either sex affected. The patient complains of excessive bleeding over a long period of years often since childhood. Positive family history is frequently obtained. Physical examination is usually negative. Ecchymoses are common but petechiae are rare. The tendency to bleed is accompanied by an increased bleeding time an essentially normal coagulation time a normal number of platelets and a normal clot retraction.

The etiology and pathogenesis of pseudohemophilia are not known. Three groups of factors are known to be concerned in the hemorrhagic disorders plasma factors platelet factors, and vascular factors. Each of these has been studied in cases of pseudohemophilia. Most data tend to classify pseudohemophilia as a disorder of the vascular apparatus.

The conclusions are as follows

Eleven cases of a hemorrhagic diathesis are presented characterized by increased bleeding time in the presence of a normal coagulation time normal blood platelet count, and normal clot retraction. An analysis of 63 similar cases in the literature is presented. These cases which have been designated as pseudohemophilia probably represent a particular disorder of the capillaries, in which capillary retractility following trauma may be inherently defective. The differential diagnosis of these cases from other types of hemorrhagic disease and the necessity for their recognition particularly from the prophylactic standpoint, are stressed. Except for easily accessible local bleeding therapy is at present ineffectual.

HAROLD F. THURSTON M.D.

Perkins, W. Pseudohemophilia; Case Study
Blood J. Hemat., 1946 1: 497

The author presents a case of a hereditary hemorrhagic disease primarily because the family history offers an unusually good opportunity to trace the genealogical background in this particular instance. The only persistent abnormality found has been prolongation of the bleeding time. Such a condition which is often hereditary and is characterized by a prolonged bleeding time in the presence of normal platelets has been previously described and referred to as pseudohemophilia, or hereditary hemorrhagic thrombasthenia.

The present case of hereditary pseudohemophilia in a 20 year old white American born male was transmitted by and occurred only in the male line. The occurrence of the condition in the male offspring of the patient's father and of the latter's second wife irrefutably proves this point.

In addition to the case history the blood findings also are presented in detail. The degree of prolongation of the bleeding time varied from day to day and was occasionally normal. Except for transient hypocalcemia with tetany no defect in the blood elements nor in clot formation was noted. There

appears to be a failure of normal capillary constriction following trauma. The author notes that this conclusion confirms the original observations of Macfarlane. Whether or not this physiological defect is entirely responsible for the prolonged bleeding time is not proved but is under further investigation.

UHL J. M., and Haberman S. Demonstration of Rh Antibodies in the Newborn and Further Evidence of the Pathogenesis of Erythroblastosis. *J. Lab. Clin. M.*, 1946 31: 1053

It is generally accepted that hemolytic disease of the newborn or erythroblastosis with a few possible exceptions, is caused by the production of Rh antibodies in Rh-negative mothers bearing Rh positive children. Although the evidence for each step in the pathogenesis of the disease is not complete the sequence of events may be outlined as follows: (1) the Rh antigen in the fetal erythrocytes is inherited from the father; (2) it gains access to the mother's circulation; (3) it evokes a maternal response of Rh antibodies; (4) these antibodies, in turn pass across the placenta into the fetal circulation or, after birth, are absorbed from the mother's milk; (5) they are adsorbed upon the infant's red cells and (6) this results in their destruction which produces anemia and jaundice. Further reactions on the part of the tissues of the newborn such as myeloid hyperplasia, ectopic hematopoiesis, and edema, then follow according to the severity of the disease.

The authors are concerned principally with the demonstration of evidence for events 4, 5, and 6 in the pathogenesis as outlined. This consists of the identification of Rh antibodies in the fetal serum, their specific adsorption on the cells of the newborn and the hemolytic destruction of Rh positive human erythrocytes in vitro. The demonstration of Rh antibodies in the infant has been difficult and uncertain. The elution technique has demonstrated the presence of adsorbed anti Rh agglutinins. This is done by removing the agglutinations from the red cells into saline solution by brief subjection to a temperature of 56° C. The authors have employed this method routinely in all cases of hemolytic disease of the newborn since their first report. Positive tests have been found in only 3 of 10 cases of erythroblastosis. The presence of antibodies adsorbed on the Rh-positive erythrocytes of the infant has never been demonstrated except when they were also present freely in the infant's serum and in the serum of the mother. The use of the blocking test slightly increases the number of positive demonstrations of fetal antibodies.

A new approach to this problem of detecting fetal antibodies is the use of antihuman globulin serum. The action is to develop an observable agglutination in which the specifically adsorbed antibodies are not able to agglutinate by themselves (blocking or incomplete antibodies). The authors have called this the developing test. They have employed this developing serum both in a test for weak antibodies in

Hill J M. and Haberman, S.: Demonstration of Rh Antibodies in the Newborn and Further Evidence of the Pathogenesis of Erythroblastosis. *J Lab Clin M* 1946 31 1053.

It is generally accepted that hemolytic disease of the newborn or erythroblastosis with a few possible exceptions, is caused by the production of Rh antibodies in Rh negative mothers bearing Rh-positive children. Although the evidence for each step in the pathogenesis of the disease is not complete, the sequence of events may be outlined as follows: (1) the Rh antigen in the fetal erythrocytes is inherited from the father (2) it gains access to the mother's circulation (3) evokes a maternal response of Rh antibodies (4) these antibodies, in turn pass across the placenta into the fetal circulation or after birth are absorbed from the mother's milk (5) they are adsorbed upon the infant's red cells and (6) this results in their destruction which produces anemia and jaundice. Further reactions on the part of the tissues of the newborn such as myeloid hyperplasia ectopic hematopoiesis, and edema then follow according to the severity of the disease.

The authors are concerned principally with the demonstration of evidence for events 4, 5 and 6 in the pathogenesis as outlined. This consists of the identification of Rh antibodies in the fetal serum, their specific adsorption on the cells of the newborn and the hemolytic destruction of Rh-positive human erythrocytes in vitro. The demonstration of Rh antibodies in the infant has been difficult and uncertain. The elution technique has demonstrated the presence of adsorbed anti Rh agglutinins. This is done by removing the agglutinins from the red cells into saline solution by brief subjection to a temperature of 56° C. The authors have employed this method routinely in all cases of hemolytic disease of the newborn since their first report. Positive tests have been found in only 3 of 20 cases of erythroblastosis. The presence of antibodies adsorbed on the Rh positive erythrocytes of the infant has never been demonstrated except when they were also present freely in the infant's serum and in the serum of the mother. The use of the blocking test slightly increases the number of positive demonstrations of fetal antibodies.

A new approach to this problem of detecting fetal antibodies is the use of antihuman globulin serum. The action is to develop an observable agglutination in which the specifically adsorbed antibodies are unable to agglutinate by themselves (blocking complete antibodies). The authors have employed the developing test. They have employed the developing serum both in a test for weak anti-

the serum of mothers and in a diagnostic test for hemolytic disease of the newborn

The methods used were as follows

1 Testing of the serum of mother and infant when isoimmunization was suspected by the test tube method of Levine and Stetson

2 Wiener's method was used to detect the incomplete blocking antibody described by Race and Wiener

3 The elution technique of Landsteiner and Miller was used routinely to attempt to demonstrate adsorbed Rh agglutinins on the cells of the blood in all cases of hemolytic disease of the newborn and on the erythrocytes of all babies whose mothers showed a positive test for Rh antibodies

4 If no clumping was seen in the agglutination test a blocking test was done with a drop of anti Rh serum and the lack of agglutination indicated the presence of blocking or incomplete agglutinins

5 For the purpose of detecting weak Rh agglutinins, incomplete antibodies or immune globulin an antihuman globulin serum was used a positive developing test indicating specifically adsorbed immune globulin was shown by definite clumping of the red cells

6 As a possible diagnostic test for erythroblastosis the developing serum was used to demonstrate the presence of antibodies specifically adsorbed on red cells in vivo

7 The demonstration of hemolytic activity of Rh serum in vitro

Ten cases were investigated. The erythroblastosis was listed as severe in 5 cases moderately severe in 2, moderate in 1 case mild in 1 and subclinical in 1. The outcome was listed as recovery in 5 cases, kernicterus in 1 case, stillborn in 1 partial recovery in 2 cases, and macerated fetus in 1 case. The treatment consisted of early transfusion in 3 cases, delayed transfusions in 3 and no transfusion in 2.

Since the developing test applied to erythrocytes of the newborn showed promise of being diagnostic for erythroblastosis, its specificity was investigated by performing routine developing tests on the erythrocytes of all cord bloods. A total of 365 developing tests on cord cells were done. Four of these did not show clinical erythroblastosis, but a background and history compatible with a subclinical isoimmunization was observed in the 4 cases. In this series developing tests were obtained on both sera and cells of 5 stillborn infants clinically not erythroblastotic. In addition there was 1 hydropic stillborn from which neither serum nor erythrocytes could be obtained. Clinical icterus was found in 4 infants negative to the developing test each of whom had the same Rh type as the mother. These were considered to be examples of physiological jaundice.

The successful removal of Rh antibodies from cord erythrocytes by elution in 3 cases of erythroblastosis is significant chiefly as a demonstration of the actual sensitization of the infant's cells preliminary to their destruction and as an opportunity to prove the specificity of this reaction by further reabsorption of

eluted antibodies on known Rh-positive red cells. This reabsorption may be indicated by agglutination or the blocking or developing tests may be required, according to the type of antibody involved. The proof that the eluted material consisted of specific Rh antibodies of the same type found in the mother's serum indicates their origin in the mother as well as their transport across the placenta from the maternal circulation into that of the fetus. The specific nature of the union of the antibody to the Rh antigen of the erythrocyte is strongly suggestive of the destructive role this antibody must play in sensitizing the red cells for their hemolysis in vivo (so characteristic of erythrocytes in vitro) by the Rh antibody is significantly demonstrated by the greater liberation of hemoglobin as compared to controls. The earlier experiments seem to give evidence that these antibodies can act as hemolytins as well as agglutinins in vitro. In comparing the relatively weak hemolysis seen in vitro with the severe hemolysis common in vivo it should be noted that in the latter cases red cell destruction may be greatly enhanced by the action of the spleen in its role of phagocytosing the slightly damaged corpuscles. Finally the titer of 1:3,000 effective in the test tube is sometimes exceeded in the mother's serum, particularly if the developing test is used to demonstrate the titer of the anti Rh immune globulin.

The elution technique in conjunction with the demonstration of hemolysis in vitro, presents additional evidence of the sequence of events in the pathogenesis of erythroblastosis. It seems to offer little as a test to identify antibodies in the infant's blood. Only in those cases that showed antibodies in the serum of the mother were the elution tests on fetal cells positive. In this series of cases it was further demonstrated that positive elution tests to demonstrate antibodies adsorbed on fetal cells were found only in those cases in which the cord serum as well as the maternal serum contained demonstrable Rh antibodies.

Since adopting the use of antihuman globulin serum as a developing test in suspected Rh isoimmunizations, the authors have been able to confirm the advantages of this serum in respect to its sensitivity to incomplete antibodies and to prove its usefulness in demonstrating Rh antibodies in the serum of mother and infant when other tests failed. Of even greater interest is the fact that the developing test not only detects incomplete or blocking antibodies but also detects specific Rh antibodies not demonstrable with agglutinating or blocking tests. The developing test also shows agglutination when agglutinating Rh antibodies are present, but the clumping reaction is much stronger than that of the agglutinating antibodies alone. In the author's case it was found that the developing titer equaled, or far exceeded, the agglutination or blocking titers. There were 2 instances of developing titers in mother or baby which were much higher than agglutinating or blocking titers and even examples of positive tests when the other 2 tests were negative. This evident

difference between the 3 tests indicates that the basic character of Rh antibodies must be different. In the case of the agglutinin which saturates the hapten and produces the visible reaction of clumping the classical antibody is seen. In the case of the blocking reaction an antibody is present which is capable of specific hapten saturation without the production of clumping. However in the case of the immune globulin, demonstrable by the developing serum the antibodies apparently are capable of specific adsorption without saturation of the available haptens and without the production of agglutination. The unique feature of this developing reaction is not saturating the available haptens is further demonstrated by the fact that after Rh-positive cells are subjected to the immune globulin no interference is found with the agglutinability of these cells with known Rh typing serum. They have designated this third type as developing antibodies. This developing antibody is of great clinical importance since it has been observed that clinical erythroblastosis may occur in the Rh-positive mother in whom no antibodies were evident. It has been noted that the observed titers of maternal antibodies have shown little or no correlation with the severity of the disease in the infant. This is because the immune substances were previously hidden to the ordinary agglutinating test. This was demonstrated in some of the cases of the authors.

The application of the developing test to the erythrocytes of the newborn shows promise of a specific test for erythroblastosis. This test may satisfy the requirements of sensitivity and specificity to fill this role. The developing test as applied to washed infant's cells is not necessarily specific for Rh antibodies but presumably would detect any specifically adsorbed antibodies.

The specificity of the developing test is supported by the negative reactions obtained in stillborn infants and cases of jaundice of the newborn in which no evidence of erythroblastosis could be found.

Analysis of the reported cases of hemolytic disease of the newborn brings out 3 therapeutic considerations. First, the use of early and adequate transfusion of Rh negative blood through the cord route in severe cases is urgently recommended. Second the infant should not be put on the breast if any Rh antibodies can be demonstrated even if no clinical erythroblastosis is apparent. The developing test on infant erythrocytes probably will be sufficiently sensitive to determine this question for Rh positive babies of Rh negative mothers.

LEROY J. KLEINGARTNER M.D.

Lozner E. L., Lemish S., Campbell A. S., and Newhouser L. R.: Preservation of Normal Human Plasma in the Liquid State. *Clinical Chemical, and Physicochemical Studies during 3 Years of Storage at Room Temperature. Blood J. Hemat.*, 1946 1: 459.

Liquid plasma is the popular form for the preservation of plasma because of its simplicity economy

and immediate availability, and despite the fact that it provides a good bacteriological culture medium even when containing bacteriostatic agents in clinically nontoxic concentrations. That plasma may be preserved in the liquid state for many months and be administered with clinical safety has been demonstrated by many investigators but the necessity for meticulous asepsis is imperative.

Previous articles concerning this study of plasma preserved in liquid state at room temperature for 3 years stated that when liquid plasma was properly prepared it may be administered to patients with safety and benefit despite the inactivation within 6 months of certain labile constituents and a slow increase in the nonprotein nitrogen and alpha amino nitrogen content, i.e. free amino acids in blood filtrates as determined by the ninhydrin-carboxy dioxide method).

This communication has as its purpose the reporting of electrophoretic, osmometric, and viscosimetric studies on plasma stored in the liquid state for 3 years and to summarize the clinical and chemical observations to date. Thus practically the work would form a reasonable basis for the determination of the expiration date of plasma preserved in the liquid state.

The authors present their results as the chemical electrophoretic, osmometric, and viscosimetric findings. Chemically it was found that there was a notable increase in the alpha amino nitrogen concentration during the first 3 years of storage; the nonprotein nitrogen concentration increased steadily for the entire period. Osmotically the stored plasma was slightly but significantly more effective than fresh plasma. Three year old plasma was slightly more viscous than fresh plasma but the difference was of no practical significance. Electrophoretic patterns showed that after 3 years of storage there was a large increase in components with the mobilities of alpha globulin and albumin at the expense of all the gamma globulin, all the fibrinogen and all of the beta globulin.

The results of questionnaires concerning some 3,384 administrations of plasma more than a year old, and a comparison of these results with those of dried plasma indicated that stored plasma was as therapeutically effective as fresh plasma and with considerably less reaction rate. However stored plasma should never be used for its immune properties or to supply blood coagulation factors in patients with a hemorrhagic diathesis. Also overenthusiastic use of stored plasma by simple dilution might result in a fall of the patient's globulin and prothrombin.

Thus liquid plasma stored for periods up to 3 years appeared to be an adequate therapeutic agent to supply colloid of human origin. Except for the fact that stored plasma is relatively isotonic, whereas human serum albumin as supplied is hypertonic, the two agents are similar in their clinical indications and precautions. Both are preserved in the liquid state at room temperature neither supplies much except a human colloid and neither should be used excessively.

The blood drawing and plasma preparation should be done with "closed systems" and meticulously aseptic and scrupulous bacteriological control throughout as liquid plasma even when containing bacteriostatic agents, may permit bacterial growth. Contaminants during preparation may multiply to dangerous proportions during preservation for even short periods.

EDWARD H. CAMP, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Tice G M: Lymphoepithelioma. *Radiology* 1946
47 116

In the present article, the development of our knowledge of tumors of the pharynx and nasopharynx is reviewed and the author has shown that lymphoepithelioma of this area has gradually come to be considered as a clinical entity the importance of which lies mainly in the fact that these tumors are quite radiosensitive and amenable to irradiation if recognized early.

The early symptoms which were listed by previous observers are (a) pain in the eye with or without diplopia, (b) pain in the ear resembling an acute infection or mastoiditis, (c) trigeminal neuralgia, (d) ptosis of an eyelid and (e) enlargement of the cervical lymph nodes.

Irradiation is believed to be the only method of treatment. For tumors in the tonsillar area, the author prefers roentgen to radium treatment (300 roentgens intraorally every other day with 50 roentgens to the adjacent cervical area on alternate days, a total skin dose of 3,000 roentgens and a total intraoral dose of 2,000 to 3,000 roentgens). For tumors in the posterior nasopharynx, 1,300 to 1,600 mgm. hours of radium are given, with intensive roentgen irradiation of the cervical lymph nodes.

Early recognition of the condition and intensive early treatment offer the only hope for cure. Distant metastases are not amenable to cure, and even symptomatic relief obtained by irradiation, is not as great as that obtained in similar metastases from cancer of the breast.

A series of 12 cases are reported. Six of the patients have died; the average length of their survival being 2½ years from the beginning of symptoms. The corresponding time of survival of the 6 patients who were alive at the time of the author's report was 2 years.

Whether transitional-cell carcinoma undifferentiated-cell carcinoma, and lymphoepithelioma are essentially the same has not been determined, but therapeutically this is of academic interest only.

HENRY L. LANE, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Rubin, L. R.: Repair of Avulsion Wounds of the Hands and Feet by the Flap Graft Technique. *Am J Surg* 1946, 72: 373

The treatment of avulsion wounds of the hands and feet in a general hospital functioning in the Mediterranean theater of operations during World War II presented definite problems which necessitated a closure technique providing a thick fatty skin cover within the shortest period of time. All of these wounds were either penetrating or perforating tendons, nerves, and bones were exposed. In most cases the bones were fractured and often fragments were missing. While many of the cases were clinically clean immediately after débridement at evacuation hospitals all were contaminated and many were infected by the time the general hospital was reached. Unless covered with a skin layer early exposed tendons and bones soon became necrotic. To prevent further loss of the deep tissue structures, and to provide for the earliest functional results all techniques of skin grafting were investigated.

The free grafts Thiersch split skin, and full thickness grafts would not take over the deep structures mentioned. A fat-containing pedicle type of graft was consequently indicated which would (1) cover exposed bone, tendon, or deep irregular muscle defects, (2) not adhere to the underlying structures, and (3) not contract excessively.

Three such types of tissue covering were available—the contiguous skin flap, the tube and the flap grafts. The contiguous skin flap or the utilization of the tissue adjacent to the wound was limited because of the relative immobility and inelasticity of the tissues of the hands and feet due to the paucity of subcutaneous fat. This was especially true for large wounds.

The tube graft was an ideal technique for covering but required at least three and more often additional operations to cover a defect. To decrease the number of the operations required the flap graft was reinvestigated and used instead of the tube graft.

Wounds of the hands and feet presented defects which could be brought to the donor sites with relative ease which obviated the necessity for tubing. An ideal situation was thus present for the use of the flap graft.

The usual donor site for hand defects was the abdomen. Practically all flaps were cut with the pedicle facing posteriorly or diagonally superiorly so as to allow the lower thoracic and posterior lumbar vertebral vessels to enter the flap. On occasion when indicated the flap base was directed superiorly or inferiorly with the source of blood supply coming from either the thoracoepigastric vessels or the su-

perficial iliacs coming up to anastomose with them. The flaps were thick and included all layers of skin and fat down to Scarpa's fascia. The size of the flap varied considerably the author did not exceed the rule of length no more than three times the width but always tried to get the widest pedicle possible.

A loose pedicle was important to avoid pull on the graft when the hand was placed on the abdomen. The part sutured to the defect was placed with normal skin tension.

The anterior lateral and medial aspects of the thigh were chosen as the best donor sites for the foot defects. In most cases the base of the flap was placed in the superior direction. However in cases in which the defect was on the lateral aspect of the foot or ankle a retrograde flap was raised the blood supply coming from the rich plexus of vessels about the knee.

In search for a more comfortable donor site the lower leg was considered but found unsuitable for several reasons. The subcutaneous tissue contained little fat, a limited blood supply and lacked contour for large defects. Another disadvantage was the lack of silent areas on the leg.

When there was doubt as to the circulation of the flap either because of the position or the size a delayed technique was used. The ideal technique called for two delays. All flaps raised were of a single pedicle type.

Only frankly necrotic tendon and bone were surgically removed before a flap was placed over the defect. Infected tendons were not debrided. All granulation and early scar tissue were removed, making sure there would be no barrier for new blood vessel penetration. Fresh skin edges were cut and then slightly undermined to facilitate suturing to the flap. Since many wounds were of the bursting as well as the lacerating type the size of the defect could often be decreased by undermining the adjacent skin edges sliding or rotating that tissue, and then suturing. Not only did this decrease the size of the flap to be raised but also it gave a regular edge to the wound. In some of the large defects of the feet it was thought advisable to decrease the size of the defect because of the difficulty in obtaining sufficient flap from the thigh. A combined $\frac{1}{2}$ and split skin graft technique was used.

There can be little doubt as to the necessity of grafting exposed tendons and nerves with a fatty cover. Since past experiences have shown that such uncovered deep structures became necrotic, covered early flaps were attempted even when they were infected.

Forty nine cases of flap graft closures were performed for deep wounds of the hands and feet, with good functional results. The very early coverage of exposed infected tendon and bone is advocated by the use of this technique. The flap graft technique

is quick and sure to take in the covering of wounds of the hands and feet with a fat containing skin cover. The principles of multiple blood transfusions and penicillin therapy are believed to be important adjuncts in the take of grafts. Early physical therapy for optimal function is a full time job for a trained nurse or an assistant who understands the problems.

JOHN L. KIRKPATRICK, M.D.

Cadenat and Monsalgeon: Gas Embolism of the Brain. The Good Effect of the Intravenous Injection of Novocain (Embolie gazeuse du cerveau. Heureuse action de la novocalinisation intraveineuse) *Mém Acad sci Par* 1946, 73 355

A woman of 47 years was operated on for calculous cholecystitis. Ten days after the operation at about 10 30 o'clock in the evening an exploratory pleural puncture was made on account of a postoperative pleural syndrome. The puncture was made with a very fine needle and did not yield any fluid, but a few minutes later the patient coughed up foamy blood. After a few seconds she lost consciousness and the pulse could not be felt. Her eyes were half open and showed horizontal nystagmus to the left. There was conjugate deviation of the head and eyes to the left. The limbs were flaccid and fell heavily; there was epileptoid tremor of both feet and a bilateral Babinski sign. At about 11 o'clock an intravenous injection of 30 c.c. of 1 per cent novocain was given. Recovery was remarkably rapid. Motion and sensation were quickly restored and after about 3 minutes the Babinski sign disappeared. At 12 30 o'clock the patient was in good condition and remained so. It seems certain that this was a case of gas embolism of the brain.

In spite of the severity of the attack, improvement had begun even before the novocain was administered and it is probable that the patient would have recovered without the injection. However, it is worth while to study such cases carefully to determine the indications and mode of action of the drugs used and the finer mechanism which produces the accidents. The differences between the findings in animal experiments and in this clinical case are discussed, and it is suggested that possibly the vasodilatation brought about by the novocain opened up new vascular networks that had previously been closed, such as the pial network and the deep subcortical capillary network.

In the discussion ISLIN described 3 cases of surgical embolism in which the intravenous injection of 10 c.c. of 1 per cent novocain gave extraordinarily rapid and favorable results.

AUDREY G. MORGAN, M.D.

Leriche, R.: The Prognosis and Treatment of Large Emboli of the Pulmonary Artery (Prognostic et traitement des grandes embolies de l'artère pulmonaire) *Lyon chir* 1946 43 357

Death from pulmonary embolism occurs suddenly. The period permitted for the observation of symptoms is brief and accurate diagnosis is correspond-

ingly difficult. Diagnosis is usually based on a history of an operation from 6 to 10 days earlier, a sudden collapse, pain, anxious expression, air hunger, dyspnea followed by cyanosis, and an irreducible fall of the blood pressure.

The most accurate means for localizing the site of embolus is to eliminate the vegetative elements by sympathetic block. This procedure clarifies the clinical picture by leaving only the effects of the mechanical block in the pulmonary circulation. Reflex phenomena may be only supplementary or they may be a major portion of the illness.

The treatment of pulmonary embolism involves first a suppression of sympathetic vasoconstrictor effect and then re-establishment of permeability of the artery. Stellate ganglion block may modify the circulatory obstruction to such a point that it remains compatible with life, also, it may indicate the need for embolectomy. If the patient's condition improves after stellate block the embolus probably has obstructed a secondary branch of the pulmonary artery rather than the main trunk. If improvement is only momentary a major trunk probably is obliterated and immediate embolectomy is necessary. The intravenous injection of 10 c.c. of 1 per cent novocaine may accomplish the same purpose and is easier to perform. However removal of the sympathetic effect produces no improvement for 2 of every 3 patients. In these one must assume that the obstruction is of the main pulmonary artery and its two branches and that operation is mandatory.

Embolectomy is a major operation requiring trained and skilled personnel with proper instruments, sterile and available for immediate use. Sixty per cent of the patients with pulmonary emboli die within 15 minutes. Others may have clots lodged in lobar branches from which they cannot be removed. Still others who may survive surgical removal of a clot may sustain a fatal recurrence.

If the operation is undertaken the author prefers a T-shaped incision with a horizontal limb 10 cm. in length over the second rib or second intercostal space. The vertical limb is placed 1 cm. to the left of and parallel to the left border of the sternum from the sternoclavicular articulation to the fourth costal cartilage. The second and third ribs are cut 7 or 8 cm. from the sternum and disarticulated. The pleura is retracted and the internal mammary vessels are ligated if necessary. The pericardium is opened at the level of the third cartilage and the aorta and pulmonary artery are identified. This important step requires skill and a knowledge of anatomy. A rubber tube is passed around the two vessels to serve as a tractor and to control circulation through the vessels. Interruption of the circulation must be brief. It is hazardous to exceed the 45 second period advocated by Trendelenburg. While the assistant holds the rubber tourniquet and obstructs the circulation the operator incises the pulmonary artery. Preliminary aspiration of the vessel may obviate confusion with the aorta. The incision in the pulmonary artery should be placed at the level of the

skin wound should be enlarged preferably in the length of the limb the deep fascial envelope freely opened, and the removal of tissue should be directed especially to damaged, soiled and devitalized muscle. Skin need be only sparingly removed. After excision the wound is left open or it is lightly filled with paraffin vaseline is sometimes applied on gauze, and an external protective dressing is applied. Insufflation of sulfonamides is not so largely used as formerly. Giving the selected sulfonamide by mouth and penicillin by intramuscular injection is the method of choice in the administration of these drugs. The initial surgical treatment of wounds still calls for observance of the fundamental principles. The excised wound should be left open and should not be closed earlier than the fourth or fifth day after excision. With the combined use of penicillin and sulfonamides closure may be accomplished earlier—in from 2 to 3 weeks—than with the use of sulfonamides alone.

Pyrexia was noted in some cases in which penicillin had been administered by continuous drip and was observed occasionally when penicillin was given intermittently.

The results were studied in 706 wounds in which the dressing had not been disturbed from the time the patient left the casualty clearing station until his arrival at the base hospital.

The incidence of infections in these wound was as follows:

Forty-nine per cent of wound which had been operated upon without the application of any bacteriostatic agent were infected. 43 per cent of wounds operated upon with the application of sulfanilamide powder were infected and 25 per cent of wounds operated upon with the application of penicillin sulfathiazole powder were infected.

The author states that immobilization of the injured part is essential for comfort of the patient and the healing of wounds. This principle applies not only to fractures but also to joint injuries and severe flesh wounds. The use of a complete nonpadded plaster cast however is dangerous if left unopened and the risk is greatest in closed or simple fractures. The swelling of a limb with intact skin and fascial envelope may produce great tension within the cast and lead to serious damage to the tissues. More emphasis is now placed on adequate and sufficiently maintained immobilization of fractures, and less emphasis is being placed on the early movement of joints.

A lowered mortality from burns has been achieved by replacing fluid loss and by the use of pressure bandages applied over copious dressings. It is now appreciated that the great reduction in the exposed skin surface in extensive burns, in which a large proportion of the body surface is swathed in bulky dressings, may lead to interference with the normal heat regulating mechanism of the body especially under tropical conditions. Excellent results have been obtained by nursing burned patients in air conditioned rooms.

JOHN L. LONGQUEST, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Tabanelli M: Frostbites Sustained in War (Cau ghementi di guerra). Arch. Ital. chir. 1943, 48 111

Of the various methods of treatment of frostbites, namely immersion of the affected extremity in hot normal saline solution diathermy x-ray irradiation, periaxillary sympathectomy and a block of the perivascular sympathetic plexus, the author prefers the last one. From 10 to 20 c.c. of the customary concentration of novocain solution or one of its derivatives, are injected in the axillary region or in Scarp's triangle respectively in order to anesthetize the sympathetic plexus of the corresponding arteries.

A few minutes after the injection one can observe a local capillary vasodilatation alleviation or complete cessation of pain, increase of the normal temperature and disappearance of the cyanosis.

Local anesthetic block consisting of the injection of novocain without adrenalin into tissues surrounding the affected area is supposed to produce similar results.

In first degree frostbites the author obtained excellent results with anesthetic block of the perivascular sympathetic nerves. From 1 to 3 injections given at daily intervals were required to produce the desired results.

In second degree frostbites the injection of novocain into the axillary region or the femoral canal may be supplemented by an injection of from 10 to 20 c.c. of novocain into the region of the second lumbar sympathetic ganglion. After the treatment a sensation of heat in the affected area is noticed by the patient vasodilatation is followed by relief of the pain and the oscillometric index demonstrates an improvement in the condition. From 1 to 3 injections at 2 day intervals are usually required to obtain relief. In 5 of 36 cases of second degree frostbite, the anesthetic block of the perivascular sympathetic nerves was supplemented by an infiltration of the second lumbar sympathetic ganglion. The results of this method were very satisfactory.

In third degree frostbites surgical procedures had to be employed. Amputation or exarticulation of the hand was done in 4 cases, while similar procedures on the feet were employed in 204 cases. Among 105 similar procedures performed on the tarsal and metatarsal bones, Lindfranc's exarticulation was done 50 times and Chopart's method was employed in 10 instances. Streptocoll was applied locally in every case.

Tubular pedicles used in skin transplantation gave good results in 85 per cent of the cases. In 56.6 per cent of the cases in which transplantation of derma and epidermis according to the Davis method was employed perfect results were obtained in 50 per cent the results were partially successful and in the remaining 16.6 per cent failures were recorded.

In 36 cases a tendon transplantation was required to correct the varus position of the foot. The lower end of the tendon of the anterior tibial muscle above

or together with the tendon of the extensor digitorum longus muscle was attached to the niche created in the cuboid bone. This operation was required to correct the deformity following the Lisfranc operation.

JOSEPH E. NABAT, M.D.

Watson, E. F. Hoge, W. G. and Koch, S. L.: Burns in Children. *Q Bull Northwest Univ M School* 1946 10 286.

The authors discuss the methods of therapy and the results of their endeavors in 266 patients admitted to the Burn Project at the Cook County Hospital. Their discussion is divided into two parts, one regarding local treatment and the other systemic therapy. Local treatment consisted of surgical cleansing under aseptic conditions, with white soap and soft cotton followed by dressing with a nonadherent fine mesh gauze which was covered by compression dressings. Petrolatum bentonite carbowax containing 10 per cent activated zinc peroxide, and penicillin were used to impregnate the gauze. The authors believe that the best results followed the use of either the penicillin gauze or the zinc peroxide carbowax gauze. Primary change of dressings was delayed for from 10 to 12 days if possible. Indications for earlier dressings were extensive saturation of the dressings or prolonged high fever. To secure clean granulating wounds for early grafting the authors found daily dressings saturated in Dakin's solution the most effective.

In the general treatment of the patients sedation was given to half. This consisted in either morphine or the barbiturates. Plasma and oxygen were given to all who had over 5 per cent of the body burned. Fluids by mouth were given as soon as tolerated and augmented by vitamins and a skimmed milk mixture to maintain protein balance. Salt solution and sodium bicarbonate were given by mouth.

Seventeen or 6.4 per cent of the patients died. There were no recoveries among the patients who had over 50 per cent of the body surface burned. All but 2 deaths occurred within 34 hours of admission. The authors both begin and conclude with the admonition that burns are an important problem, and that their care can be undertaken only in a hospital. The best first aid is to wrap the child in a clean sheet and to bring it to a hospital for care.

WILLIAM C. BECK, M.D.

Gardner, C. E.: Air Force Battle Casualties. An Experience with Acute Injuries of 839 Battle Casualties from the Eighth Air Force. *Arch Surg* 1946 53 387.

Air force crews in combat are subject to injury not only from enemy gunfire but also from the effects of cold or anoxia at high altitudes from burns or injury from crash landings or parachute jumps or from a bizarre assortment of accidents within a plane in flight the commonest of which is being caught in a revolving gun turret. Of the 839 patients whose cases constitute the basis of this report 645 had battle wounds from missiles 140 had battle injuries from

plane crashes 26 had battle injuries from parachute jumps and 28 had injuries from plane accidents.

Of the 645 patients injured by missiles 69 per cent were wounded in the extremities 20 per cent in the head and neck and 11 per cent in the trunk. Of the wounds of the extremities fractures occurred in 25 per cent, neural injuries in 8 per cent and major arterial injuries in 5.5 per cent. There was a low incidence of penetrating thoracic and abdominal wounds as compared with wounds of ground forces in the field because of the effectiveness of body armor worn by crews of heavy bombers in combat.

Treatment was begun by the crew in the plane before it landed after which the wounded man was seen by his flight surgeon and taken from the plane to the medical station on the field. Here first aid measures begun on the plane were checked and continued and plasma was given if necessary. Patients were then transferred to the hospital where they were received in the shock ward for resuscitation study and preparation for operation. Shock was treated with transfusions of whole blood. Reactions to transfusions had to be guarded against. Hemolytic reactions are more prone to follow large multiple or repeated transfusions. Alkalinization of the urine was carried out in an endeavor to prevent the renal damage resulting from hemoglobinemia and hemoglobinuria.

Wounds of the soft parts were treated by excising all devitalized tissue, removing foreign bodies irrigating with isotonic solution of sodium chloride dusting lightly with sulfanilamide powder in most cases inserting loosely a gauze strip covered with petrolatum to the depth of the wound, and applying a voluminous dressing snugly. No harm resulted from the local use of sulfanilamide in wounds left open for later secondary suture. Healing of the wounds in which sulfanilamide was not used was not essentially different from healing of sulfanilamide treated wounds. Sulfadiazine was given routinely by mouth until after secondary closure of the wound had been carried out. Penicillin was given to patients with major wounds. Pentothal sodium was the anesthetic used in most cases.

Wounds of the scalp, face, and all serous cavities were closed after excision. All others were left open and not dressed until 5 days later when the patient was returned to the operating room and secondary closure was done. For associated wounds of the skeletal system requiring traction skeletal traction was used. Where traction was not necessary well padded plaster casts were applied. Internal or external skeletal fixation was not used. First dressings were done in the operating room 5 days after débridement at which time the wounds were closed if possible by suture or skin graft.

Wounds penetrating the skull or brain were treated by scalp débridement, removal of loose fragments of skull enlargement of the skull defect removal of traumatized brain by suction with special care to remove indriven bone fragments and pains taking hemostasis, with the use of muscle packs or

a good skin covering at the earliest moment rather than to allow them to granulate and develop extensive contractures or to allow healed scarred epithelium which is tense and thin to become excoriated with secondary ulceration.

Contracture of the hand due to various etiology—lacerations, penetrating objects, shrapnel and bullet wounds, in which soft tissue is the primary tissue injured and in which heavy scar develops with healing—may be superficial and involve only the skin and subcutaneous tissue of the hand or it may extend deeper and involve all the soft structures underlying it including the tendons, joints and nerves. Usually the condition is not relieved permanently by conservative treatment and surgery is ultimately required.

Many of the patients, fortunately, have only one or two digits or merely parts of digits traumatically amputated, and a useful hand can be obtained with the remaining digits if the amputation stumps are covered satisfactorily. Usually the skin over the stumps is thin and atrophic, or painful neuromas are present which prevent even light pressure on these areas. Frequently because of pain a patient will not use the other remaining functioning digits of his hand with resulting joint stiffness which further increases his disability. Surgery will relieve these conditions and even apparent lengthening of a short deformed digit can be obtained by deepening the adjacent web spaces.

A number of the injuries seen are produced by sharp penetrating objects which have healed more or less per primam but in which the original injury has divided the tendons either flexors or extensors. In the treatment of wounds in the field it is impractical to do primary tendon repair, and frequently because the wounds are dirty it is inadvisable to repair them later at the station hospital even should the patient arrive within 12 hours the so-called relatively safe period for primary tendon repair. This condition is amenable to treatment and an attempt should be made to restore function by the surgical procedure of secondary tendon repair with a tendon graft. A technique of tendon grafting is described.

All wounds of the hand if left open are contaminated but fortunately most of them heal without apparent extensive infection. There is a group of cases in which virulent infectious processes develop with destruction of tissue and resultant deformities many of which are contracture deformities of a general nature. The infectious process destroys the smooth gliding action of the tendons and joints disturbs general nutrition and the entire hand becomes painful and useless as far as function is concerned.

There is a large group of combat injuries in which the injury is extensive and all the various tissues are involved to a greater or lesser extent. These cases are combination problems of orthopedic, plastic, and neurosurgery and the problem is one of restoring all remaining structures to as near a functioning status as possible. Extensive surface scarring is

usually present and the circulation is impaired. It is necessary to replace the surface covering with a pedicle graft after the scar has been excised. This improves the general condition of the hand. The orthopedic and neurosurgical problems should be corrected before the final tendon reconstruction is undertaken.

In evaluating the extent of damage of an injured hand a history of the condition together with the previous treatment is essential. This takes time and patience on the part of both surgeon and patient and frequently a hasty diagnosis as to the condition becomes disappointing to both surgeon and patient alike when the end results are tabulated.

It is of paramount importance to make a very careful examination of the entire extremity as well as the injured hand. Local signs may have remote causes. The general condition of the hand should be observed including the circulation, the general state of nutrition and the atrophic changes. The general picture should then be outlined. Each part of the hand is checked separately for motion, pain and sensory disturbance. X-ray examination is imperative to check bone changes and deformities. The disability is noted and studied, and the anatomical basis for it worked out. This is important from the standpoint of diagnosis and evaluation and also from that of its correction. When one is able to visualize the pathological condition one is able to outline the procedure to be followed in the rehabilitation of the hand and to give a prognosis. The author believes there is no justification for subjecting a patient to the ordeal of an operative procedure which is long laborious and will offer him only little possibility of improvement. By reviewing the condition carefully, the surgeon is able to avoid this in most cases. If the hand is nothing more than a nonfunctioning mass of painful scarred tissue resulting from wounds and subsequent infection one would be performing a surgical feat rather than a sound surgical procedure to even attempt to rehabilitate it. Perhaps, amputation with prosthesis would be the solution.

After elective operative procedure is decided upon certain preoperative care is necessary. The original injury must be well healed. No induration or retraction of tissue to healing should be present. In the case of a tendon injury 3 to 6 months should elapse before secondary repair. In cases in which heavy scarring is binding and acts as a constriction—a condition which interferes with nutrition—a preliminary operation is necessary in which the scar tissue should be removed and good tissue cover supplied in the form of a pedicle graft. The patient should be encouraged to take occupational therapy also as an adjunct to physiotherapy.

Hand surgery is always difficult even when optimum operative conditions are available. Good lighting is necessary. General anesthesia or the anesthetic of choice. It is essential to provide a bloodless field in which to work and not to damage important structures, as well as to aid in making a

clean anatomical dissection. An Esmarch tourniquet is used to express the blood in the hand and forearm before inflating the cuff. While the Esmarch tourniquet is in place the blood pressure tourniquet is inflated to between 240 to 260 and, after clamping each tube to secure the pressure the Esmarch tourniquet is removed and the operation is started.

Incisions are made in the hand along the flexion creases and not over points of pressure. Mid-lateral incisions are made along the digits. Good exposure should be obtained. It is extremely important to be gentle in retracting skin flaps and in handling normal structures in order not to traumatize the tissue thus minimizing the formation of postoperative scarring. All scar tissue should be removed.

If extensive scar tissue is present and the skin is adherent to underlying structures, a pedicle graft is used to cover the defect after excision of the scar. This provides a good covering and subcutaneous fat under which tendons can glide and also healthy tissue to replace the scar thereby improving the general nutrition of the hand. Subsequent operations for nerve work or tendon grafting can then be approached through healthy tissue. After the dissection is complete the tourniquet is released. It is well to remember that after release of the tourniquet pressure should be maintained on the wound with moist sponges for 5 minutes because of the initial hyperemia. This saves unnecessary clamping of oozing points and then only active bleeders need be secured. After the operation is completed careful closure of the wound is necessary. A pressure dressing is always necessary in hand surgery to prevent undue oozing and to prevent hematoma from developing postoperatively. This can be accomplished by applying fine meshed gauze to the surface of the wound and stuffed gauze which can be compressed with gauze bandage. If fixation of the part is necessary a molded plaster or metal splint can be applied.

Elevation of the limb postoperatively for any surgery done on the hand is essential in order to minimize postoperative discomfort and swelling. Inspection of the wound can be done from 7 to 10 days after operation by opening the bandages without disturbing the hand and forearm from its splint. Sutures can be removed at this time and the dressing folded together again and rebandaged. Elevation of temperature and pain and throbbing sensations in the hand call for inspection at any time.

In the case of tendon work fixation of the hand in plaster for 3 weeks without motion is maintained and support is then given by elastic bands. The patient is encouraged to move his hand actively immediately after its removal from the cast with elastic traction used as a safeguard against sudden pull on the healing structures. Occupational therapy to engage the patient in intricate manipulative work and hand exercises, and good physiotherapy with the patient's full co-operation are essential for good results.

Rehabilitation of the injured hand is most instances probably one of the most difficult tasks

which the surgeon is called upon to perform. A careful examination and planning, together with meticulous surgery this work can be accomplished with satisfactory results in many cases. Good co-operation on the part of the patient in taking active hand exercises and following physiotherapy treatments is most essential for good results.

JAMES E. KIRKPATRICK, M.D.

Shambaugh, P.: Postoperative Wound Infection—An Evaluation of Factors Concerned with the Resistance of the Tissues to Infection. *Q. Bul Northwest. Univ. M. School* 1946, 20: 176.

The factors which have been ascribed as lowering tissue susceptibility to infection are sensibility to the effect of irritating suture materials, imperfect hemostasis and physical and chemical trauma. The author believes that this opinion has been accepted uncritically without substantial clinical or experimental proof, and has undertaken to apply investigative methods to determine its soundness. He thinks that sensibility has rightly been accused of lowering tissue resistance to infection as the percentage of suppurating wounds in a series of 2,360 controlled hemiorchiectomies was 30 per cent higher in the patients over than in those under 50 years of age.

Experiments are cited to show that wounds closed with catgut are more liable to wound infection than those sutured with silk. The author finds no appreciable difference between silk, cotton, and possibly steel wire, although the last appears to be the most advantageous from the standpoint of infection. Furthermore, he finds no difference between treated and untreated silks. Nylon is dismissed because of the difficulty in retaining knots.

Imperfect hemostasis as a cause of reduced tissue resistance is discussed in some detail, and several experiments are reviewed. The author thinks that blood itself is not a good culture medium unless some chemical irritant has been added. A table of Fleming's is quoted to show that leucocytic activity is maintained in hematomas for only 2 days, after which there is a precipitous decline in such activity. Therefore after this period the evacuation of hematomas may be fraught with a certain amount of danger if bacteria are thereby introduced. The introduction of serum into a wound, however, was associated with a high percentage of wound infection.

Dedication by drying wounds under a lamp, surprisingly did not reveal any increase in the incidence of wound infection. Experiments with various bactericidal agents introduced into grossly contaminated wounds, revealed that they are largely innocuous and may even be harmful. Simple lavage with physiological salt solution appeared to be of some value in grossly contaminated wounds, but only to the extent of removing particulate matter, not in effecting any sterilization of the tissues. Soap solutions and other stronger bactericides probably produce an adverse effect because of their inhibitory or lethal influence on polymorphonuclear leucocytes.

WILLIAM C. BUCK, M.D.

ANESTHESIA

Nicholson, M. J., and Eversole, U. H. Neurological Complications of Spinal Anesthesia. *J Am Med Ass* 1946 132: 679.

Headache, septic and aseptic meningitis, arachnoiditis, neuritis, myelitis, and the cauda equina syndrome have been the complications most frequently reported following spinal anesthesia.

These cauda equina complications are generally brought to the anesthetologist's attention because the patient fails to regain the use of his lower extremities at the usual time. Loss of motor and sensory function is generally found to involve the lumbosacral nerve distribution. The loss of bowel and bladder function is the most ominous part of the entire clinical picture and the return of function when it occurs, is extremely slow.

The clinical manifestations of the lesions of the cauda equina might be explained by damage to the lumbosacral region of the cord to the conus medullaris or to the nerves of the cauda equina, but it seems more probable that the maximal damage is to the latter. A résumé of several possible ways in which such damage might occur follows:

1. Direct trauma as the sole cause of the anesthetic complication can fairly well be eliminated because of the thousands of diagnostic lumbar punctures that have been performed without any similar complication.

2. The rapid onset of most of these complications seems to preclude infection as an etiological factor.

3. It seems that only those nerves exposed to the greatest concentration of the drug are affected. The

lesion is maximal in those roots of the cauda equina which are closest to the place where the drug was injected.

4. Another consideration is the possibility that spinal anesthesia may act as a precipitating factor in the evolution of certain pre-existing neurological affections.

It is almost impossible to determine from the literature the true incidence of neurological complications following spinal anesthesia since the reports show great variation. There have been 21,000 patients at the Labey Clinic who have received tetracaine hydrochloride for spinal anesthesia since 1934. Five neurological complications resulted. In 3 cases lesions of the cauda equina type developed and in 2, the patients were later found to have a cerebrospinal fluid block from metastatic carcinoma. Two patients developed a peroneal neuropathy. In addition 2 patients in whom postspinal neurological disturbances developed and who were suspected of having permanent sequelae were found on further investigation and operation to have been suffering from tumors of the spinal cord.

There is a report of 13 cases in which neurological complications developed after spinal anesthesia. A detailed regimen for the prevention of postspinal neurological complications is presented.

A patient who shows a delay in the return of motor and sensory function following spinal anesthesia should be considered for emergency treatment and warrants immediate attention. Certain of these complicated cases may require special and intensive treatment before the patient can be rehabilitated.

MARY FRANCES FOX, M.D.

duce stretching and separation of the angular and posterior temporal arteries and their branches. In the anteroposterior projection, the position of the carotid remains unchanged and the bifurcation into the anterior and middle cerebral arteries has the configuration of a rectangular compressed U.

Tumors of the occipital lobe and adjoining posterior inferior part of the temporal lobe show less characteristic angiographic signs. In lateral arteriograms moderate elevation and forward crowding of the angular and posterior temporal arteries may be seen. The terminal branches of these vessels are definitely spread and distended as are the arborizations of the posterior cerebral artery, provided that vessel is filled. More anteriorly, the compressed arteries of the sylvian group exhibit a tendency to coil together. On the anteroposterior projection the midline shift of the anterior cerebral artery is slight or even absent. The vein of Labbe may be shifted downward and anteriorly.

Space-occupying lesions of the frontal lobe deform to a variable degree the supracallosal segment of the internal carotid artery, the anterior two-thirds of the anterior cerebral artery and its branches, and the beginning of the middle cerebral artery with its frontal ascending (rolandic) branches. The most characteristic sign of all unilateral frontal tumors is the considerable displacement and localized stretching of the anterior cerebral artery to the opposite

side. As a rule this midline shift is more marked in frontal neoplasms than in hemispherical tumors of any other location.

Representative of the subfrontal tumors are the meningiomas of the olfactory groove. These are large neoplasms arise from the floor of the sphenoid fossa and compress the orbital surface of the frontal lobe and suprasellar region; they show bilateral as often than unilateral development. On arteriograms taken in lateral projection the supracallosal, subcallosal segments of the anterior cerebral artery are displaced upward and posteriorly forming an anteriorly concave arc around the lesion (Fig 5). In large tumors, the supracallosal portion of the carotid and the pericallosal knee of the anterior cerebral artery may be pushed backward. Unilateral olfactory groove meningiomas displace mainly the subcallosal portion of the anterior cerebral artery to the opposite side (Fig 6).

The group of prefrontal tumors comprises mainly astrocytomas and meningiomas (arising from the anterior portion of the falx and superior longitudinal sinus). On lateral arteriograms the carotid siphon and the beginning of the sylvian vessels are pushed slightly backward and downward. The anterior cerebral artery is displaced backward so that the curve of the vessel around the knee of the corpus callosum is blunted without losing its forward convexity. The smaller forward branches of the anterior cerebral

Fig. 3 (List and Hodges.) Anteroposterior arteriogram of subdural hematoma.

Fig. 4. Anteroposterior arteriogram of parietal meningioma. Arrow points to circulation at tumor attachment.

Fig. 5

Fig. 6

Figs. 5 and 6. Arteriograms of sarcomatous olfactory groove meningioma lateral and anteroposterior projection

artery appear distended and spread apart. Much more impressive changes are observed in anteroposterior projection. There is major displacement of the anterior cerebral artery across the midline underneath the free edge of the falx and in contrast to most other hemispherical tumors the distance between the anterior and middle cerebral arteries is greatly increased. The subcallosal and pericallosal portions of the anterior cerebral artery form a smooth round bulge and due to stretching the extended frontopolar branch leaves the main vessel without undulation. Diagrammatically the figure outlined by the carotid bifurcation and the anterior and middle cerebral arteries resembles an open O.

Premotor tumors such as the astrocytomas, oligodendrogliomas, and meningiomas, are commonly encountered. The carotid siphon as seen in the lateral projection is compressed sometimes forming an apparent sharp angle anteriorly. Instead of following a normal diagonally ascending direction the initial portion of the sylvian group is depressed taking a horizontal or even downward convex course. It is important to observe the configuration of the ascending frontoparietal artery. This vessel, which has roughly the shape of the Greek letter Ψ (psi) is difficult to trace in the normal brain, because of its redundancy. In premotor tumors, the frontoparietal artery is displaced downward and posteriorly with its terminal branches separated. The anterior cerebral artery may be depressed in its supracallosal segment and the callosomarginal branches separated. If the lesion is in parasagittal location but the polar vessels show little or no spreading. The angiographic picture revealed by the anteroposterior projection is similar to that of prefrontal tumors, with the exception that the principal midline shift occurs a little higher at the knee of the anterior cerebral artery which is projected just below the edge of the falx.

In cases of frontotemporal tumors one observes meningiomas of the lesser sphenoidal wing growing underneath the frontal lobe into the beginning of the sylvian fissure glioblastomas of the posterior inferior frontal and opercular regions and diffuse astrocytomas. In the lateral projection the supracallosal portion of the carotid forms with the middle cerebral artery a straight, diagonally ascending line. The sylvian group continues in the same direction or is as often a little elevated or depressed. The ascending frontoparietal artery is markedly stretched and its two widely separated terminal branches form a triangular pattern. Due to the stretching of the sylvian vessels the origin of the anterior cerebral artery is projected clear from superimposed vascular shadows. The pericallosal curve of the anterior cerebral artery is elevated and widened (similar to the picture seen in hydrocephalus). In the anteroposterior projection the anterior cerebral artery exhibits the bulge across the midline typical of frontal tumor the middle cerebral artery may have a tendency to diagonal elevation as is observed in tumors of the temporal lobe. On venograms the internal cerebral vein may appear displaced upward and posteriorly. Space occupying lesions of the parietal lobe depress the sylvian vessels and the pericallosal artery. Thus the distance between the anterior and middle cerebral systems appears to be reduced in the lateral projection. There is only moderate midline displacement of the posterior part of the anterior cerebral artery because the resistant falx yields little to pressure yet there may be characteristic notching of the anterior parts of the vessel underneath the falx. In parietal tumors poor filling of the terminal cortical arteries has been observed. Presumably, the intravascular pressure of the inflection is insufficient in the smaller branches to overcome the compression by the tumor.

Neoplasms of the superior parietal region (parasagittal meningiomas, gliomas) depress and sometimes separate the pericallosal and callosomarginal arteries. The vessels of the sylvian group may not be much deformed, except for separation of the terminal branches of the posterior parietal and angular arteries. Inferior parietal tumors, commonly glioblastomas, depress considerably the sylvian vessels but displace little or not at all the anterior cerebral artery in the vertical plane. In the lateral projection the sylvian group appear compressed and take an unusual horizontal or downward convex course instead of the normal diagonal fanlike arrangement. The terminal branches (anterior and posterior parietal and angular arteries) leave the sylvian group almost at right angles and ascend vertically being widely separated from each other. On venograms, some separation of the superior cerebral veins may be noted, and the vein of Labbe may be displaced downward.

In tumors of the basal ganglia and thalamus a presumptive diagnosis can be made when there is evidence of moderate hydrocephalus with the anterior cerebral artery remaining in its normal midline position. In certain lesions of the basal ganglia, however this vessel describes an unusual forward and upward bulge similar to that observed in posterior inferior frontal tumors. If the small arteries of the anterior perforate space (lenticulostriate and lenticulo-optic vessels) are visible in the anteroposterior film, they appear stretched and displaced laterally. The anterior choroidal artery may be seen displaced downward and posteriorly describing a semicircle around the optic tract and pulvinar. This is almost a pathognomonic sign for thalamic neoplasm, but unfortunately the choroidal vessel is not always visible.

FRANK L. HOWARD M.D.

Mannheimer B.: The X Ray Appearance of Pharyngeal Palsy. *Brit. J. Radiol.* 1946, 19 383.

Fluoroscopic examination of the pharynx during attempted deglutition of thick barium paste reveals the following characteristic findings:

1. Atonic enlargement of the pharynx.
2. Retention of large quantities of barium in the pyriform sinuses and epiglottic valleculae.
3. Smooth tapering of the barium column at the junction of the pharynx and esophagus.
4. Normal first or oral phase (passage of bolus into oropharynx), but absence of the active second phase (passage through pharynx into esophagus).
5. Failure of the larynx to close during deglutition with consequent aspiration of the barium into the trachea.
6. Absent feeble, or irregular movements of the hyoid bone during swallowing as determined by kymographic study.

Other points favoring but not diagnostic of paralysis are:

1. Sudden onset of severe dysphagia, almost complete inability to swallow solids after an illness of short duration.

2. Regurgitation of food through the nose.
3. Complete absence of pain in spite of severe dysphagia.
4. Roentgenographically normal trachea and retropharyngeal space.

The author reports 2 cases that were referred to the x ray department with a clinical diagnosis of possible malignancy. The characteristic findings were observed in both cases. The final diagnosis was pharyngeal palsy due to bulbar paralysis.

R. B. LEVIN, M.D.

Rakofsky M., and Knickerbocker T. W.: Roentgenological Manifestations of Primary Pulmonary Coccidioidomycosis. *Am. J. Roent.* 1945, 50 47.

The organism, *coccidioides immitis*, is endemic primarily in California and to a lesser extent in Arizona and Texas. This organism exists in two forms: a vegetative phase which exists in nature, and a parasitic spore which is found in the tissue of the host. It is not transmissible from man to man.

Primary coccidioidomycosis manifests itself in two stages. In the first stage the clinical picture is one of an upper respiratory infection with cough, fever, chest pain, erythema nodosum, and positive pulmonary roentgenograms. This clinical picture endures from 3 to 6 weeks, and usually the patient recovers.

In a few cases, over a period of years, the disease may become secondary with skin and bone lesions, or, within a matter of weeks, may assume a fulminating character ending fatally with a miliary or meningitic picture. The mortality of chronic coccidioidomycosis is 50 per cent.

Fortunately most cases of coccidioidomycosis remain in the first stage. The dark skinned race, entering an endemic area for the first time, is found to be most susceptible. Many of these cases are found to progress into the stage II type. The only residual of the stage I group is a positive skin test which may persist as long as 20 years.

The pulmonary roentgen picture consists of nodules, peribronchial infiltration, confluent consolidation, pleural effusion, hilar adenopathy and cavitation.

1. Nodules occur either unilaterally or bilaterally anywhere in the lung. Their size varies from 5 mm. to 3 cm. The nodules either resolve in a few weeks or become fibrotic.

2. Interstitial or peribronchial inflammation occurs in hilar or basilar regions.

3. Confluent consolidation occurs anywhere in the lungs and resolves somewhat slowly. Pleural effusion may also be present.

4. Hilar adenopathy is associated with peribronchial infiltration.

5. Cavities are thin walled in the periphery of the lung fields with parenchymal involvement and resolve within 8 weeks.

The pulmonary roentgen picture is one of a combination of the described findings. They may be of proportion to the clinical picture.

Fig. 1 (Rakošky M and Knickerbocker T W) The nodular lesion. History and clinical features: White, male aged 30 had never previously been in California or Arizona. Admitted on October 26, 1943 with chest pain, cough, malaise and mild fever. Coccidioides (1:100) skin test was positive. Eosinophiles 13 per cent, sedimentation rate 26 mm. Complement fixation test strongly positive. Roentgen findings a, November 1, 1943. Roentgenogram shows a 2 cm. single, homogeneous nodule in the

right midpulmonary field. edges are well defined. There is associated peribronchial thickening and haziness at the right cardiophrenic angle. Note the smaller sharply circumscribed nodule of slight density at the periphery of the left midpulmonary field. b December 27, 1943 shows beginning and partial clearing of the previously described nodule in the right midpulmonary field. The right cardiophrenic angle has cleared. The smaller nodule on the left is still present. Disposition: return to duty

Diagnosis is made on the basis of a history of exposure erythema nodosum, eosinophilia positive skin test, positive complement fixation precipita-tion tests positive chest roentgenograms and, in the final analysis isolation of the spores from the sputum by culture

A series of 60 cases of coccidioides is reported. Twenty five were of the dark skinned race with low resistance. Autopsy findings in 2 of the cases are described. One was a rather unusual case of active tuberculosis and coccidioidomycosis

MAURICE D SACHS M D

Lenz M L: Tumor Dosage and Results in Roentgen Therapy of Cancer of the Breast *Am J Roentg* 1946 56 67

Two hundred and six cases of breast carcinoma in which roentgen therapy was the method of treatment were used as a basis for the present study by the author

From 1923 to 1929 78 patients received postoperative irradiation the tumor dose ranged from 300 to 3,300 roentgens. Medium low voltage (130 k.v.) was used to the chest wall and axilla, the supraclavicular regions and the opposite axilla. The dose was repeated within a 2 to 3 months. This treatment was found to be inadequate. Eight patients showed skin metastases. The survival rate was not dependent on treatment but on the preoperative extent of the lesion

Results with increased voltage have not been encouraging. Therefore roentgen therapy following

mastectomy is given only when residual or recurrent tumor is still present

From 1933 to 1937 38 patients received irradiation preoperatively and 44 received irradiation alone. The tumor dose was 4,500 roentgens. High voltage (500 k.v.) and tangential fields were used. All of the patients (82) had involvement of the axilla. Skeletal or lung metastases were present in 18 per cent of the 44 patients treated with irradiation alone. Only 1 patient survived 5 years. The resolution of the primary lesion following irradiation did not influence the course of the disease. In spite of the high tumor doses (4,500 r) given tumor cells were still demonstrable in the studied specimens

From 1938 to 1941 46 patients who had not been operated upon were given a tumor dose of 6,000 roentgens, or more. Sequelae due to the high dose were minor and were not permanent. In 23 of 31 patients the breast tumor and axillary tumor disappeared. 10 of these patients were living and well 5 years later

Radical mastectomy wherever possible is still advocated as the treatment of choice. Criteria as to operability are those postulated by Haagensen and Stout of the Presbyterian Hospital, New York. If the lesion is inoperable it is advisable to give a tumor dose of above 6,000 roentgens to the breast and axilla. Breast cancers with axillary involvement should be classified as operable or inoperable rather than temporizing with preoperative and postoperative plans of roentgen irradiation

MAURICE D SACHS, M D

Farfaglia, P. L.: Retrograde Abdominal Aortography. A Contribution to the Study of the Abdominal Aorta and Ilac Arteries. *Radiology* 1946, 47 344.

The technique of retrograde abdominal aortography is simple. The femoral artery is exposed by blunt dissection under local anesthesia at the level of Scarpa's triangle: a trocar 1.5 mm. in diameter is inserted and 50 c.c. of a 70 per cent diodrast solution are injected in 1½ to 3 seconds. A tourniquet at the root of each lower extremity prevents the passage of the contrast medium downward. The maintenance of a uniform pressure during the injection is important. The author devised an apparatus permitting the injection of 25 c.c. of the opaque medium per second under a constant pressure of 15 pounds. The first roentgenogram is made when 40 c.c. of the solution have been injected and the second one immediately afterward. The trocar is then withdrawn, a suture is placed in the adventitia of the artery and the wound is closed. The administration of phenobarbital the night before and of morphine hypodermically one hour prior to the injection helps in obtaining better relaxation.

The method is of value in syphilitic arteritis showing dilatation or obliteration of the arteries and the different types of aneurysm, in arteritis obliterans, in degenerative lesions which occur more commonly at the end of the abdominal aorta, and in the iliac arteries, leading to dilatation, elongation or tortuosity of the vessels and often associated with calcium deposition. The author was even able to observe valvular kinks that retarded the circulation considerably. Surgical removal of these kinks improved the circulation.

The article is illustrated with some typical roentgenograms. T. LAUCURIA, M.D.

Meehan, I.: A Roentgenographic Study of Spondylolisthesis, with Special Reference to Stability Determination. *Radiology* 1946, 47 349.

The author describes an improved method for the detection of spondylolisthesis and the determination of the slipped vertebral body.

Since a defect of the pars interarticularis is found in most cases of spondylolisthesis, an accurate roentgen visualization of this part of the spine is important. The term "pars interarticularis" refers to the isthmus of bone lying between the superior and inferior articular processes. Actually this segment is a portion of the lamina and separates the vertebral body pedicles, superior articular processes, and transverse processes from the inferior articular processes and the spinous process. It is best visualized in the oblique view. In case of bilateral defect the detection is usually made in straight lateral views, the vertebral body becoming susceptible to anterior displacement.

The fact that the posterior margin of the slipped vertebral body bears a definite relationship to the posterior margins of adjoining vertebral bodies can be used to measure spondylolisthesis quite accu-

ately. Routine roentgenograms of the lumbosacral spine are made in recumbent anteroposterior, lateral, and both oblique views. When defects of the pars interarticularis are found, additional roentgenograms are made in erect positions, with the patient standing straight, flexing the spine, and extending the spine. The lateral projections are used to measure the degree of spondylolisthesis. Four landmarks are chosen: A is the posterior inferior lip of the vertebral body above the one in question; B is the posterior superior lip of the vertebral body below the one in question; C is the posterior lip of the superior surface of the involved vertebral body; and D is the posterior inferior lip of the involved vertebral body. Lines are drawn through AB and CD and extended until they intersect if possible. Occasionally they will appear parallel or superimposed. The intersection in the normal almost invariably occurs at the level of, or below the vertebral body in question. In spondylolisthesis the lines intersect above the vertebral body in question. The author designated from 10 to 30 degrees as indicative of slight slipping, from 30 to 50 degrees of moderate slipping, and of more than 50 degrees of severe slipping. If the lines are parallel, they are 3 mm. or less apart in the normal, up to 1 cm. apart in slight slipping, from 1 to 2 cm. apart in moderate slipping, and more than 2 cm. apart in severe slipping. The instability of the slipped vertebra is detected by studying the degree of anterior displacement in the various positions of the spine. A variation greater than 1 millimeter or 2 degrees is considered relatively significant of instability.

The number of cases examined by the author from April 19, 1943 to March 19, 1944 are divided into two series. The first includes 1,131 cases seen during a period of 23 months while the hospital was in a rear echelon and the second 530 cases seen during a period of 6 months while the hospital was in a forward echelon. For various reasons, which the author expounds in detail, this latter series is the more representative. Whereas in the first series defects of the pars interarticularis were noted in 5 per cent of the total, in the second series they were noted in 11.7 per cent. Correspondingly, the cases of spondylolisthesis, or borderline spondylolisthesis, increased from 5.6 per cent to 6.5 per cent. Stability studies were made in 44 per cent of the cases of spondylolisthesis of the first series and in 82 per cent of the second which gave an incidence of instability of 39 per cent and 50 per cent, respectively.

The most frequent sites of involvement were the fifth lumbar vertebra, in 73.7 per cent of the cases, and the fourth lumbar vertebra in 14.7 per cent.

Bilateral defects of the pars interarticularis occurred more than twice as frequently (69 per cent) as unilateral defects. Approximately three-fifths of patients with bilateral defects had definite spondylolisthesis, one-fifth had borderline spondylolisthesis, and the remaining one-fifth had no spondylolisthesis. One half of the slipped vertebral bodies were shown to be unstable under conditions of stress, but even if

no instability could be demonstrated the presence of localized lipping sclerosis and apophyseal joint changes indicated strain upon the adjoining supporting structures.

The article is abundantly illustrated with diagrams and typical roentgenograms.

T LEUCOTIA M.D

Scott, L. D. and Tarleton G. J.: Pyridoxine Hydrochloride (Vitamin B₆) in the Control of Radiation Sickness: Preliminary Report *Radiology* 1946 47 386

In 1941 the authors installed a shock-proof 220 kv. p. roentgen therapy unit, yielding an output of 50 r/min with 200 kv. 0.5 mm. of copper plus 1 mm. of aluminum filtration at a distance of 50 centimeters. This output permitted the irradiation of a patient with larger daily doses than was the custom formerly a fact which on the other hand led to more pronounced radiation sickness.

Since that time to combat the radiation sickness, the authors administered 50 mgm. of nicotinic acid i. d. routinely to all patients receiving 200 kilorads of roentgen therapy.

In April, 1945 another change was made. In order to shorten the rather long duration of the series of irradiation the daily dose was raised from 300 to 600 roentgens. In this manner the treatment time for various types of malignant growths was reduced by approximately one half. To overcome the radiation sickness incidental to the additional increase of the dose the authors started to give 25 mgm. of pyridoxine hydrochloride intravenously after each roentgen treatment, supplementary to the nicotinic acid.

The method was used in 35 cases. The first 20 of these are presented in tabular arrangement. The development of radiation sickness was prevented in nearly all of the patients.

T LEUCOTIA, M.D

Glenn J. C. Jr., and Reeves, R. J. Treatment of Radiation Sickness with Trasentine and Trasentine-Phenobarbital Preliminary Report. *Radiology* 1946, 47 392

A number of articles dealing with the value of vitamins particularly thiamine chloride pyridoxine and nicotinic acid in the treatment of radiation sickness, have appeared in the literature. Jenkinson and Brown called attention to the possible value of amphetamine and d-desoxyephedrine.

Wallace, after roentgen studies on a series of patients receiving roentgen therapy over the pelvis, reported changes strongly suggesting that the immediate cause of the nausea, diarrhea and abdominal pain may be intestinal and sphincter spasm. With this possibility in mind the authors tried antispasmodic therapy for the purpose of relieving the symptoms.

The present preliminary report refers to 65 unselected patients so treated. They are arranged in an all-inclusive table. The antispasmodic drug was trasentine (75 mgm. per tablet) which was given alone in the first 26 patients the total dosage ranging from 225 to 1000 mgm. per day (1 to 3 tablets 3 to 4 times a day). A second group of 32 patients received trasentine-phenobarbital tablets (20 mgm. of trasentine plus 20 mgm. of phenobarbital) at the rate of from 1 to 2 tablets 3 times a day. Finally a third group of 7 patients including mostly patients with nausea and diarrhea were treated with a combination of trasentine-phenobarbital (1 tablet 3 times a day) and trasentine (1 to 3 tablets 3 to 4 times a day).

The conclusion is reached that trasentine and trasentine-phenobarbital are valuable adjuncts in the treatment of radiation sickness. No toxic effect was noticed but trasentine had a tendency to depress the appetite to some degree.

T LEUCOTIA M.D

the fact that hyperplasia induced by the sex hormones is a functioning hyperplasia, while that induced in the thyroid by thyrotrophic is functionless, may possibly be a determining factor in the relationship between simple and neoplastic growth of tissue.

JOSEPH K. NARAY, M.D.

Hughes, R. R.: Post Penicillin Jaundice. *Brit. M. J.* 1946 2: 685

While working in a military general hospital in India, the author noted that a large number of patients with infective hepatitis admitted to the medical ward gave a history of having received a course of penicillin injections within the previous 7 months. Post-penicillin jaundice was likened to post-arsphenamine jaundice.

It was concluded that the condition was transmitted from patient to patient by means of contaminated syringes. Experiments were carried out, and the mechanism by which the contamination occurred was discussed.

C. FRED GOTTSCHALK, M.D.

Hueper W. C. The Significance of Industrial Cancer in the Problem of Cancer. *Occup. M.* 1946 2: 90

Occupational cancer is of great importance not only as a public health problem, but also because it may be considered as a human equivalent of experimental cancer in animals.

Exogenous carcinogenic factors may elicit malignant growths through one of the following three mechanisms:

1. The first group of occupational carcinogens consists of agents which apparently cause a cancerous cellular transformation by acting directly on the cellular substrate. Substances contained in tar pitch asphalt, soot mineral oil and those represented by certain aromatic amines (benzidine, aniline) may serve as examples.

2. The second group is formed by agents which exert carcinogenic properties indirectly by changing some normal chemical constituent of the cells or tissue fluid in such a way that it becomes endowed with carcinogenic properties. This mechanism may be active in the development of cancers caused by radiating energy nickel asbestos, and arsenic.

3. In a third group those carcinogens are found which have neither primary nor secondary blastogenic properties, but which elicit functional disturbances in certain organs such as the liver pituitary adrenal glands and the gonads. The functional abnormalities may in turn lead to the development of circumstances possessing carcinogenic qualities.

The age factor represented by the relative age or the average life span has no significant part in determining the degree of susceptibility to carcinogenic agents.

There is no concrete evidence that a genetic predisposition plays an important role in the incidence of occupational cancer.

A multicentric development of cancer is frequent with occupational carcinogenesis. This

has been observed in from 15 to 30 per cent of industrial carcinoma. The excessive frequency of primary multiplicity of occupational cancer is evidently an expression of a mild carcinogenic stimulation. JOSEPH K. NARAY, M.D.

DUCTLESS GLANDS

Rall, E. P.: Factors Affecting Survival in the Adrenalectomized Rats. *Endocrinology* 1946 39: 17

In the course of studies on the effects of endocrine metabolism in adrenalectomized black rats maintained on diets deficient in the fat-soluble vitamin B it was observed that survival after adrenalectomy was greatly prolonged when the diet was supplemented with a rice bran extract. The present report is concerned with the comparative effects of adrenocortical extract, deoxycholic acid acetate and calcium pantothenate without 1 per cent sodium chloride solution on the survival of adrenalectomized black rats.

Experiments were made in both black and white rats on diets deficient in pantothenic acid. In the adrenalectomized rats, the survival of animals was given a 1 per cent sodium chloride solution and continued on the deficient diet. In the diet and injections of the adrenocortical extract or deoxycholic acid acetate or on the diet supplemented with calcium pantothenate. The group of animals was treated in a similar manner but no sodium chloride was given.

When the sodium chloride was omitted, the survival was sharply curtailed. When 1 per cent sodium chloride was given the addition of calcium pantothenate to the diet resulted in a remarkably long period of survival, 50 per cent of the rats surviving for 150 days. The survival with calcium pantothenate and sodium chloride was less than that obtained when the rats received both deoxycholic acid acetate and sodium chloride and the deficient diet. The importance of sodium chloride to the survival of pantothenate and treated adrenalectomized rats is shown by the fact that withdrawal of sodium chloride resulted in death.

EXPERIMENTAL SURGERY

McCall, J. W. and Moore, A. L.: Reoperation for Paralyzed Vocal Cord. *Laryngoscope* 1946 57: 577

This article is a preliminary report on the results in the experimental animal, of nerve resection for vocal cord paralysis, and subsequent development of regeneration of the recurrent laryngeal nerve.

Analysis of one vocal cord only of the experimental animal, showed weakness, voice change, and a decrease of the throat characteristic of the recurrent laryngeal nerve. The results of the reoperation on the vocal cord and the results of the reoperation on the vocal cord.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Barcroft H., and Edholm, O. G.: Sympathetic Control of the Blood Vessels of Human Skeletal Muscles. *Lancet* Lond. 1946 313

The question whether or not the sympathetic nervous system supplies the blood vessels in muscle and maintains vasoconstrictor tone during muscular inactivity is of fundamental importance in peripheral vascular disease. Animal investigations on the whole seem to point in that direction. Sympathetic nerve endings have been identified histologically in the walls of blood vessels in cat muscle. Increase in the blood flow through muscle in the dog and cat has been observed after section of the sympathetic nerve supply. Nevertheless, general opinion is against the presence of sympathetic tone in the vessels in human muscle. Recent work in Belfast however has convinced the author that such tone exists, and a summary of the evidence is submitted.

The technique of demonstrating sympathetic vasoconstrictor tone in the blood vessels of human skeletal muscles is described.

The blood flow in muscles is more than doubled by the release of sympathetic tone. Heating the body relaxes the vasoconstrictor tone in the blood vessels supplying muscles. Vasoconstrictor tone gradually returns to the blood vessels of sympathetomized subjects. Vasodilatation takes place in the muscles of the forearm after fainting, except in sympathetomized subjects. Therefore this vasodilatation is due to nervous control. It is shown that vasodilatation in the forearm muscles is not due merely to removal of vasoconstrictor tone but that it is at any rate in part, mediated by vasodilator nerves.

JOHN E. KIRKPATRICK, M.D.

Lisbow, A. A., MacLean P. D., Burnstead, J. H., and Welt L. G.: Tropical Ulcers and Cutaneous Diphtheria. *Arch. Int. M.* 1946, 78 355

Ulcerative lesions of the skin are frequent in the tropics and virulent *Corynebacterium diphtheriae* are often isolated from them. Diphtheritic ulcers have been described by many with a host of different terms: erythema, desert sore, Veldt sore, gariga, etc. They are significant because of their source of *Corynebacterium diphtheriae*, their relation to nasopharyngeal diphtheria, their sequelae of myocarditis and neuritis and because of the symptoms from the skin condition per se. Although only 1 per cent of cases of nasopharyngeal diphtheria in the temperate zones develops cutaneous diphtheria in the middle East and northern India, diphtheritic lesions of the skin occur frequently and out of proportion to the cases of nasopharyngeal diphtheria. In these regions it appears endemic. This is true of military personnel foreign to these regions as well as of the

natives. Such lesions were commonly observed during both the first and the second world war.

An extensive study was made of diphtheritic ulcers found in 174 patients involving men in Salpau, the Solomon Islands, and Leyte. In addition Schick tests were done on many natives of these areas. A comprehensive record of each ulcer was taken. Intense parasitological and bacteriological studies were made. Cultures of the ulcer, nose, and throat were taken. Schick tests and examinations disclose neurological lesions, were carried out.

Tryptose agar without dextrose, and containing 5 per cent of human blood, was employed as a culture medium. Direct examination of the ulcer cradle was done and an attempt made to predict the subsequent bacteriological investigation. In one per cent the presence of *Corynebacterium diphtheriae* was correctly diagnosed in 83 1/2 per cent of the cases. Certain aspects of culturing were emphasized.

1. *Corynebacterium diphtheriae* grows better in a slightly alkaline medium (about pH 7.6).

2. *Corynebacterium diphtheriae* closely resembles certain other hemolytic *corynebacterium* common at these locations, which were probably *C. erythrogenes* and *C. pyogenes*, but which the authors have designated as *Corynebacterium hemolyticum*. Although they appear alike on Loeffler's medium, on blood agar plates the colonies have large zones of beta hemolysis surrounding them.

3. By testing for toxigenicity by the intracutaneous inoculation of guinea pigs and rabbits, 14 per cent of the hemolytic *corynebacterium* proved toxigenic. The atoxic forms were relatively more common in carriers. All strains of the nonhemolytic *corynebacterium* proved nontoxigenic.

Corynebacterium diphtheriae was found concomitantly with diphtheroids, beta hemolytic streptococcus, *Corynebacterium hemolyticum*, *Staphylococcus albus* and aureus. The older ulcers yielded relatively fewer toxic bacilli than the more recently acquired ones.

Regardless of the wide geographic distribution of these ulcers, a remarkably similar appearance was present among them. Usually a history of trauma or insect bite could be elicited and in the majority of instances the troops were active rather than resting. The initial lesion, for example a scratch, began to enlarge instead of healing, later it deepened and the edges first red and edematous, became rolled. Granulations failed to rise, but the bottom receded continuously, causing the ulcer to be rounded, unscrapable, indolent, and treatment-resistant. Usually about the sharply defined sore there was a zone of induration, erythema, and violaceous pigmentation. In atypical cases the condition developed in pre-existing epidermophytosis. The lesions were multiple in 75 per cent of the cases and appeared on the extremities in 99 per cent.

Corynebacterium diphtheriae was occasionally isolated in shallow ulcers impetiginous dermatitis chronic paronychia desquamative and ulcerative dermatitis, and unexplained sinus tracts of the feet.

In a large number of instances it was possible to predict from the clinical appearance of the lesion whether or not *Corynebacterium diphtheriae* would be found although it is emphasized that the lesion is not pathognomonic.

Complications noted as occurring in patients with diphtheritic ulcers were

1. Unexplained tachycardia without electrocardiographic changes or fever. This disappeared when the ulcers healed.

2. In 2 patients with a positive Schick reaction a striking erythema and edema occurred about the ulcers following antitoxin administration. This is comparable to the Francis reaction noted in pneumococcal infections.

3. Numerous troops were tested for the Schick reaction in order to determine the relation between the test and the incidence of ulcer. The percentage of patients with diphtheritic ulcers reacting positively to the test was approximately twice that of persons who reacted positively in general.

In 174 patients with cutaneous diphtheria nose and throat cultures revealed *Corynebacterium diphtheriae* in 19 instances. Of these, 10 had clinical pharyngeal diphtheria and 2 had fibrinous rhinitis. There were 6 pharyngeal carriers and 1 nasal carrier. In these patients ulcers generally antedated the upper respiratory infection.

Many cases of peripheral neuritis and pharyngeal and ocular palsy were seen in the Pacific area hospitals, a few of which were associated with nasopharyngeal diphtheria. The authors state that neuritis can also be secondary to cutaneous diphtheria. In instances of cutaneous diphtheria the cranial nerves were rarely involved. The symptoms of diphtheritic neuritis secondary to cutaneous lesions were those of paresthesias followed by weakness of the extremities. The deep reflexes were decreased or absent. Proprioception was often disturbed. The spinal fluid protein was elevated and although pleocytosis was not observed changes in the Lange curves were frequent.

Hospitalization isolation bed rest and moist dressings were the most commonly used procedures for treatment. Patients treated in the Out Patient Department with sulfonamide pastes and dry dressings continued to have their ulcers for many weeks and served as a prolific source of *Corynebacterium diphtheriae*. The final treatment of choice consisted of bed rest and the application of an isotonic solution of penicillin to the ulcers.

Ulcers containing atoxic organisms healed more rapidly than those with toxigenic bacilli. Serum treatment did not seem beneficial. The authors state that antitoxin should be used as it acts as a prophylactic in preventing the serious complication of nasopharyngeal diphtheria. In cases in which antitoxin was given late it did not prevent neuritis.

Locally applied penicillin caused the gram negative bacillary flora to replace the gram positive organisms. *Corynebacterium diphtheriae* although sensitive to sulfonamides in vitro was not affected by these drugs when they were placed in the ulcers. Other special forms of treatment included the application of casts to secure immobilization excision of the ulcer, and skin grafts although these usually failed to take.

Considerable evidence has accumulated that cutaneous diphtheria is an important source of the spread of bacilli to the nose throat and skin. In 7 persons diphtheritic infections developed before ulcers were recognized as being due to *Corynebacterium diphtheriae*. These cross infections included diphtheritic paronychias, abscesses pharyngitis and nasopharyngitis.

The incidence of diphtheritic ulcers exceeds that of nasopharyngeal diphtheria and carriers. Among patients with diphtheritic ulcers the incidence of carriers was much higher than in the general population. The authors suggest that troops returning from areas endemic for cutaneous diphtheria may serve as carriers for spread to the civilian population. The existence of large reservoirs of diphtheria in the tropical natives was demonstrated. The high incidence of cutaneous diphtheria accounts for the gradual immunization of the natives and the early age at which this process occurs. The frequent occurrence of diphtheria in the tropics is due to (1) the warm moist condition of the skin (2) the intimacy among the population and (3) the unhygienic state due to infrequent washing.

C. FREDERICK KITTLE, M.D.

Cantarrow A., Paschke, K. E. Stansley J., and Rothenberg M. S.: The Influence of Sex Hormones upon the Hepatic Lesions Produced by 2 Acetaminofluorene. *Cancer Res* 1946 6 610

The observation of the susceptibility of the stimulated goitrous thyroid to the tumor-producing action of the carcinogen 2-acetaminofluorene suggested an investigation of the influence in this connection of other agents that stimulate the growth of specific tissues. For this purpose androgenic and estrogenic hormones were chosen.

Excessive quantities of an exogenous or endogenous estrogen and androgen were found to accelerate and intensify the development of cystic and neoplastic hepatic lesions induced in Sherman rats by 2 acetaminofluorene. In the authors opinion this phenomenon may be related to the role of the liver in the intermediary metabolism and excretion of the sex steroids. It is interesting to note that thioauracil appeared to exert a strikingly protective action on the liver as far as the development of both cystic and neoplastic lesions is concerned.

In rats receiving thioauracil simultaneously with the carcinogen no tumors occurred in the hyperplastic target organs of the sex hormones, in sharp contrast to the high incidence of tumors of the thyroid gland. The authors advance the following hypothesis

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Barcroft H. and Edholm, O. G.: Sympathetic Control of the Blood Vessels of Human Skeletal Muscle. *Lancet*, Lond. 1946 2 513

The question whether or not the sympathetic nervous system supplies the blood vessels in muscle and maintains vasoconstrictor tone during muscular activity is of fundamental importance in peripheral vascular disease. Animal investigations on the whole seem to point in that direction. Sympathetic nerve endings have been identified histologically in the walls of blood vessels in cat muscle. Increase in the blood flow through muscle in the dog and cat has been observed after section of the sympathetic nerve supply. Nevertheless, general opinion is against the presence of sympathetic tone in the vessels in human muscle. Recent work in Belfast however has convinced the author that such tone exists, and a summary of the evidence is submitted.

The technique of demonstrating sympathetic vasoconstrictor tone in the blood vessels of human skeletal muscles is described.

The blood flow in muscles is more than doubled by the release of sympathetic tone. Heating the body relaxes the vasoconstrictor tone in the blood vessels supplying muscles. Vasoconstrictor tone gradually returns to the blood vessels of sympathetomized subjects. Vasodilatation takes place in the muscles of the forearm after fainting, except in sympathetomized subjects. Therefore, this vasodilatation is due to nervous control. It is shown that vasodilatation in the forearm muscles is not due merely to removal of vasoconstrictor tone but that it is, at any rate in part, mediated by vasodilator nerves.

JOHN E. KIRKPATRICK, M.D.

Uebow, A. A., MacLean, F. D., Burnstead, J. H., and Welt, L. G.: Tropical Ulcers and Cutaneous Diphtheria. *Arch. Int. M.*, 1946, 78 255.

Ulcerative lesions of the skin are frequent in the tropics, and virulent *Corynebacterium diphtheriae* are often isolated from them. Diphtheritic ulcers have been described by many with a host of different terms: erythema, desert sore, Veldt sore, ganglia, etc. They are significant because of their source of *Corynebacterium diphtheriae*, their relation to nasopharyngeal diphtheria, their sequelae of myocarditis and neuritis, and because of the symptoms from the skin condition per se. Although only 1 per cent of cases of nasopharyngeal diphtheria in the temperate zones develops cutaneous diphtheria, in the middle East and northern India, diphtheritic lesions of the skin occur frequently and out of proportion to the cases of nasopharyngeal diphtheria. In these regions it appears endemic. This is true of military personnel foreign to these regions as well as of the

natives. Such lesions were commonly observed during both the first and the second world wars.

An extensive study was made of diphtheritic ulcers found in 174 patients involving men in Saipan, the Solomon Islands, and Leyte. In addition Schlick tests were done on many natives at these areas. A comprehensive record of each case was taken. Intense parasitological and bacteriological studies were made. Cultures of the ulcer area, ex-throat were taken. Schlick tests and examinations to disclose neurological lesions, were carried out.

Tryptose agar without dextrose, and containing 5 per cent of human blood, was employed as a culture medium. Direct examination of the ulcer crabs was done and an attempt made to predict the subsequent bacteriological investigation. In one group the presence of *Corynebacterium diphtheriae* was correctly diagnosed in 83 1/2 per cent of the cases. Certain aspects of culturing were emphasized:

1. *Corynebacterium diphtheriae* grows better in slightly alkaline medium (about pH 7.6).

2. *Corynebacterium diphtheriae* closely resembles certain other hemolytic *corynebacterium* common at these locations, which were probably *C. ovis* and *C. pyogenes*, but which the authors have designated *Corynebacterium hemolyticum*. Although they appear alike on Loeffler's medium, on blood agar plates the colonies have large zones of beta hemolysis surrounding them.

3. By testing for toxigenicity by the intracutaneous inoculation of guinea pigs and rabbits, 44 per cent of the hemolytic *corynebacterium* proved toxigenic. The atoxic forms were relatively more common in carriers. All strains of the nonhemolytic *corynebacterium* proved nontoxigenic.

Corynebacterium diphtheriae was found concomitantly with diphtheroids, beta hemolytic streptococci, *Corynebacterium hemolyticum*, *Staphylococcus albus* and *aureus*. The older ulcers yielded relatively fewer toxic bacilli than the more recently acquired ones.

Regardless of the wide geographic distribution of these ulcers, a remarkably similar appearance was present among them. Usually a history of trauma or insect bite could be elicited and in the majority of instances the troops were active rather than resting. The initial lesion, for example a scratch, began to enlarge instead of healing; later it deepened and the edges, first red and edematous, became raised. Granulations failed to rise, but the bottom accrued continuously causing the ulcer to be rounded, serpiginous, indolent, and treatment-resistant. Usually about the sharply defined sore there was a zone of induration, erythema and violaceous pigmentation. In atypical cases the condition developed in pre-existing epidermophytosis. The lesions were multiple in 75 per cent of the cases and appeared on the extremities in 99 per cent.

Corynebacterium diphtheriae was occasionally isolated in shallow ulcers impetiginous dermatitis chronic paronychia, desquamative and ulcerative dermatitis, and unexplained sinus tracts of the feet. In a large number of instances it was possible to predict from the clinical appearance of the lesion whether or not *Corynebacterium diphtheriae* would be found, although it is emphasized that the lesion is not pathognomonic.

Complications noted as occurring in patients with diphtheritic ulcers were

1. Unexplained tachycardia without electrocardiographic changes or fever. This disappeared when the ulcers healed.
2. In 2 patients with a positive Schick reaction a striking erythema and edema occurred about the ulcers following antitoxin administration. This is comparable to the Francis reaction noted in pneumococcal infections.

Numerous troops were tested for the Schick reaction in order to determine the relation between the test and the incidence of ulcer. The percentage of patients with diphtheritic ulcers reacting positively to the test was approximately twice that of persons who reacted positively in general.

In 174 patients with cutaneous diphtheria nose and throat cultures revealed *Corynebacterium diphtheriae* in 19 instances. Of these, 10 had clinical bacterial diphtheria and 2 had fibrinous rhinitis. There were 6 pharyngeal carriers and 1 nasal carrier; these patients ulcers generally antedated the respiratory infection.

Many cases of peripheral neuritis and pharyngeal and ocular palsy were seen in the Pacific area hospital, a few of which were associated with nasopharyngeal diphtheria. The authors state that neuritis can also be secondary to cutaneous diphtheria. In instances of cutaneous diphtheria, the cranial nerves were rarely involved. The symptoms of diphtheritic neuritis secondary to cutaneous lesions were those of paresthesias followed by weakness of the extremities. The deep reflexes were weak or absent. Proprioception was often disturbed. The spinal fluid protein was elevated and although pleocytosis was not observed changes in the Lange curves were frequent.

Hospitalization, isolation, bed rest and moist dressings were the most commonly used procedures for treatment. Patients treated in the Out Patient Department with sulfonamide pastes and dry dressings continued to have their ulcers for many weeks and served as a prolific source of *Corynebacterium diphtheriae*. The final treatment of choice consisted of bed rest and the application of an isotonic solution of penicillin to the ulcers.

Ulcers containing atoxic organisms healed more rapidly than those with toxigenic bacilli. Serum treatment did not seem beneficial. The authors state that antitoxin should be used as it acts as a prophylactic in preventing the serious complication of nasopharyngeal diphtheria. In cases in which antitoxin was given late it did not prevent neuritis.

Locally applied penicillin caused the gram negative bacillary flora to replace the gram positive organisms. *Corynebacterium diphtheriae* although sensitive to sulfonamides in vitro was not affected by these drugs when they were placed in the ulcers. Other special forms of treatment included the application of casts to secure immobilization excision of the ulcer and skin grafts, although these usually failed to take.

Considerable evidence has accumulated that cutaneous diphtheria is an important source of the spread of bacilli to the nose, throat, and skin. In 7 persons diphtheritic infections developed before ulcers were recognized as being due to *Corynebacterium diphtheriae*. These cross infections included diphtheritic paronychia, abscesses pharyngitis and nasopharyngitis.

The incidence of diphtheritic ulcers exceeds that of nasopharyngeal diphtheria and carriers. Among patients with diphtheritic ulcers the incidence of carriers was much higher than in the general population. The authors suggest that troops returning from areas endemic for cutaneous diphtheria may serve as carriers for spread to the civilian population. The existence of large reservoirs of diphtheria in the tropical natives was demonstrated. The high incidence of cutaneous diphtheria accounts for the gradual immunization of the natives and the early age at which this process occurs. The frequent occurrence of diphtheria in the tropics is due to (1) the warm moist condition of the skin (2) the immunity among the population and (3) the unhygienic state due to infrequent washing.

Cantarrow A. Paschke, K. E., Stansley J., and Rothenberg, M. S.: The Influence of Sex Hormones upon the Hepatic Lesions Produced by 2-Acetaminofluorene. *Cancer Res.*, 1945, 6: 610

The observation of the susceptibility of the stimulated goitrous thyroid to the tumor producing action of the carcinogen 2-acetaminofluorene suggested an investigation of the influence in this connection of other agents that stimulate the growth of specific tissues. For this purpose androgenic and estrogenic hormones were chosen.

Excessive quantities of an exogenous or endogenous estrogen and androgen were found to accelerate and intensify the development of cystic and neoplastic hepatic lesions induced in Sherman rats by 2-acetaminofluorene. In the authors' opinion this phenomenon may be related to the role of the liver in the intermediary metabolism and excretion of the sex steroids. It is interesting to note that thionauril appeared to exert a strikingly protective action on the liver as far as the development of both cystic and neoplastic lesions is concerned.

In rats receiving thionauril simultaneously with the carcinogen no tumors occurred in the hyperplastic target organs of the sex hormones in sharp contrast to the high incidence of tumors of the thyroid gland. The authors advance the following hypo-

thesis the fact that hyperplasia induced by the sex hormones is a functioning hyperplasia, while that induced in the thyroid by thiouracil is functionless, may possibly be a determining factor in the relationship between simple and neoplastic growth of tissue.

JOSEPH K. NARAT, M.D.

Hughes, R. R.: Post Penicillin Jaundice. *Brit. M. J.* 1946, 2: 685

While working in a military general hospital in India, the author noted that a large number of patients with infective hepatitis admitted to the medical ward gave a history of having received a course of penicillin injections within the previous 7 months. Post penicillin jaundice was likened to post-arphen amine jaundice.

It was concluded that the condition was transmitted from patient to patient by means of contaminated syringes. Experiments were carried out, and the mechanism by which the contamination occurred was discussed.

C. FERN GONZALEZ, M.D.

Hueper W. C.: The Significance of Industrial Cancer in the Problem of Cancer. *Occup. M.* 1946, 2: 190.

Occupational cancer is of great importance not only as a public health problem, but also because it may be considered as a human equivalent of experimental cancer in animals.

Exogenous carcinogenic factors may elicit malignant growths through one of the following three mechanisms:

1. The first group of occupational carcinogens consists of agents which apparently cause a cancerous cellular transformation by acting directly on the cellular substrate. Substances contained in tar pitch, asphalt, soot, mineral oil and those represented by certain aromatic amines (benzidine, aniline) may serve as examples.

2. The second group is formed by agents which exert carcinogenic properties indirectly by changing some normal chemical constituent of the cells or tissue fluid in such a way that it becomes endowed with carcinogenic properties. This mechanism may be active in the development of cancers caused by radiating energy, nickel, asbestos, and arsenic.

3. In a third group those carcinogens are found which have neither primary nor secondary blastogenic properties, but which elicit functional disturbances in certain organs such as the liver, pituitary, adrenal glands and the gonads. The functional abnormalities may in turn lead to the development of circumstances possessing carcinogenic qualities.

The age factor represented by the relative age or the average life span has no significant part in determining the degree of susceptibility to carcinogenic agents.

There is no concrete evidence that a genetic predisposition plays an important role in the incidence of occupational cancer.

A multicentric development of cancer is frequent with occupational carcinogenesis. This phenome-

non has been observed in from 15 to 30 per cent industrial carcinomas. The excessive frequency of primary multiplicity of occupational cancers is evidently an expression of a relatively potent carcinogenic stimulation.

DUCTLESS GLANDS

Raill, E. P.: Factors Affecting Survival in Adrenalectomized Rats. *Endocrinology* 1946, 39: 20.

In the course of studies on the alteration of mineral metabolism in adrenalectomized black rats maintained on diets deficient in the filtrate factors of vitamin B it was observed that survival after adrenalectomy was greatly prolonged when the diets were supplemented with a rice bran extract. The latter present report is concerned with the comparative effects of adrenocortical extract, desoxycorticosterone acetate, and calcium pantothenate, with or without 1 per cent sodium chloride solution, on the survival of adrenalectomized black rats.

Experiments were made in which black rats were fed diets deficient in pantothenic acid and/or adrenalectomized. Following adrenalectomy 50 per cent of animals was given a 1 per cent sodium chloride solution and continued on the deficient diet alone, while the diet and injections of the adrenocortical hormone or desoxycorticosterone acetate, or on the diet supplemented with calcium pantothenate. The second group of animals was treated in a similar manner, but no sodium chloride was given.

When the sodium chloride was omitted, regardless of hormone administration or dietary supplement, the survival was sharply curtailed. When 1 per cent sodium chloride was given the addition of calcium pantothenate to the diet resulted in a remarkably long period of survival, 50 per cent of the animals surviving for 150 days. The survival with calcium pantothenate and sodium chloride was longer than that obtained when the rats received hormone diet, 100 plus sodium chloride and the deficient diet. The importance of sodium chloride to the survival of the pantothenic acid treated adrenalectomized rat was shown by the fact that withdrawal of salt resulted in death.

HARRY W. FINE, M.D.

EXPERIMENTAL SURGERY

McCall J. W., and Hoerr N. L.: Reinnervation of the Paralyzed Vocal Cord. *Laryngoscope*, 1946, 56: 537.

This article is a preliminary report on the results in the experimental animal of nerve suture after vocal cord paralysis, and submission of a method for regeneration of the recurrent laryngeal nerve by means of anastomosis to the vagus nerve.

Paralysis of one vocal cord only does not endanger life. Voice weakness, voice change and frequent clearing of the throat characterize this condition. Pressure on the vagus or recurrent laryngeal from a tumor in the neck or mediastinum is a frequent cause of vocal cord paralysis.

Paralysis of both vocal cords endangers life for if both cords are paralyzed they assume the median position and close the glottis. The paired posterior cricoarytenoids are the only abductor muscles of the arytnx, and when they are paralyzed the patient cannot open the glottis on inspiration. If the cricoarytenoids do not open the glottis on inspiration the flaccid cords are drawn closer together by the inspired current of air which causes the inspiratory crowing sound which is typical of bilateral abductor paralysis. Thus, it is an inspiratory dyspnea. The patient has no difficulty with expiration as the force of the current of air is strong enough to separate the flaccid cords enough to expel the air.

Contrary to general belief there is little voice change in bilateral abductor paralysis. There is not as much voice alteration in bilateral vocal cord paralysis as in unilateral paralysis, because in bilateral paralysis the vocal cords assume the median position.

Thyroid disease and the sequelae of thyroidectomy are the most frequent causes of bilateral paralysis. Neurological conditions such as cerebral lues are the next most frequent cause. During a thyroidectomy the recurrent laryngeal nerves may be severed or they may be so constricted by scar tissue post-operatively as to cease to function.

The operative procedures for the relief of bilateral abductor paralysis necessitate a certain amount of mutilation of the larynx. If the breathing is improved the voice is impaired. Hence, if short-cutting of an injured recurrent laryngeal nerve by anastomosing the vagus to the recurrent peripheral to the lesion is accomplished it would render a mutilation of the larynx unnecessary and restore the normal function of the vocal cord.

The recurrent laryngeal nerve is usually injured in the region of the inferior thyroid artery so an approach to the recurrent nerve should be above the point where it had been severed or compressed. The recurrent laryngeal nerve leaves the groove behind the trachea and esophagus and turns laterally in the neck to enter the larynx just below the inferior cornu of the thyroid cartilage. This is above the point where it is usually injured. With a collar (horizontal) incision about 1 cm. below the cricoid cartilage beginning lateral to the sternomastoid on the side to be done and extending the incision across the midline of the neck the recurrent nerve is identified and isolated as far down in the neck as possible. The sternomastoid is retracted laterally, and the vagus is identified, dissected as far as possible in the neck, and is severed and drawn under the common carotid and strap muscles. The recurrent nerve is then severed. The vagus stump is usually long enough to suture to the recurrent stump without tension and the finest arterial silk suture that can be obtained is used.

The operation was performed on 4 dogs with good results in 3 the failure was believed to be due to the use of too large suture material and faulty technique. In the other 3 dogs the vocal cord movements

were effective and permitted a normal bark.

Kershner D. Hooton T. C., and Shearer E. M.
Production of Experimental Portal Hypertension in the Dog; Anatomy of the Hepatic Veins in the Dog. *Arch. Surg.*, 1946, 53, 425

Venous congestion of the liver by constriction of the posterior vena cava anterior to the kidneys has previously been produced. Death usually follows in from 5 to 10 hours after the complete ligation of the vena cava just above the renal veins. If the animal survives, such a procedure results in congestion not only of the hepatic and portal systems, but also of the systemic regions drained by the vena cava caudad to the obstruction particularly the kidney.

The present work was undertaken with the object of producing hepatic congestion and accompanying portal hypertension in the dog without the associated congestion of the systemic regions. A procedure has been devised for the production of venous congestion in the dog mechanically a 3 stage operation. This method has the advantage of avoiding congestion of the systemic regions caudad to the occlusion. It does so by taking into account the complex nature of the relationship between the hepatic veins and the posterior vena cava and by making use of the collateral circulation from the caudad regions of the body to the heart thus preventing caudal congestion.

That portal hypertension occurs in animals subjected to the operational procedure described has been noted in extensive physiological studies carried out on many of the dogs especially on the 4 animals that survived all the operations. The portal pressure is increased after the first operation. By partial occlusion of the postcaval vein caudad to the liver increased portal resistance is built up and the blood is forced into channels which are inconspicuous under normal conditions. These anastomoses connect the portal and systemic veins, and thereby promote a path for the return of blood from the splanchnic area to the right side of the heart. When the new collateral circulation has developed stage 2 can be performed, with minimum damage to the kidneys. When stage 3 of the operation has been performed the portal pressure is increased still further. With an original pressure of about 8 cm. of water there is no filtration from the capillaries into the abdominal viscera. With an increased pressure of 15 cm. or more of water there is increased filtration. The slow rise in pressure is evidenced by the latent period of the development of ascites, after the posterior vena cava has been partially occluded below the heart. Ascites in these animals was not observable until 7 to 20 days after operation. Increasing quantities of ascitic fluid were then formed as measured by changes in weight and by the large amounts of fluid that could be withdrawn.

Forty six dogs were used in the experiments. The operative procedure is described.

SAMUEL KAHN M.D.

Blaine G : The Uses of Plastics in Surgery *Lancet* Lond., 1946, 2 525

Plastics are chemical substances of high molecular weight. They are deformable and under suitable conditions retain an acquired shape. They are versatile since the end product can be given different physical properties for instance some plastic might be made into a very hard object a flexible mass, an adhesive film or even into a yarn. They doubtless will make new surgical procedures possible. Generally they are grouped according to their physical and chemical behavior and divided into absorbable and nonabsorbable materials, according to living tissue reaction. A few interesting facts follow.

Of the plastics used in bone surgery acrylics have been found most useful. Despite little reaction early they tend to become loose, often after 6 months, although no tendency to work themselves out has been observed.

Acrylics are currently used with the "dental impression technique. This necessitates a 2 stage operation the first stage being the taking of the impression and the second the fitting of the prosthesis. The technical difficulties of this procedure led to the 1 stage operation which may be done in one of two ways. The first consists of the setting of activated acrylic dough by means of the ultraviolet ray. The second method makes use of the thermoplastic properties of the preformed unplasticized methyl methacrylate sheet. This sheet heated to 130 C and while soft is molded into the exact shape desired. This shape is retained on cooling. Either of these methods can be completed within 15 or 20 minutes.

Acrylic jointcaps have been used in the treatment of arthritis of the hip and in the reconstruction of the small joints of the hand. Acrylics have been used as spinal jackets and they have been used as Gunning splints in the treatment of fractures of the edentulous jaw.

Some of the disadvantages of acrylics are that the temperature at which the plastic is moldable is quite uncomfortable for the patient and the operator they do not absorb moisture and therefore allow sweat to accumulate pruritus to develop and a foul odor to manifest itself. Occasionally a severe dermatitis has resulted.

Acrylic contact lenses and artificial eyes do not break easily but are very easily scratched and are rather expensive. The polyvinyl plastic substances have been used as drainage tubes, for anesthetic air ways and for soft tissue prostheses, but they cannot be worn indefinitely and are photosensitive. Plastic chemistry has introduced the very popular nylon suture material.

The greatest use of the absorbable plastics has been in the field of hemostasis. Such articles as oxidized cellulose fibrin foam and gelatin foams have proved of great value surgically.

The latest development in absorbable plastics is a derivative of seaweed known collectively as the alginate group. Certain alginate products are absorbable in tissue sterilizable by heat, and compatible with penicillin. They have been found satisfactory as "puncture patches" over scleral defects. Alginate gels have been reported useful in the sealing of bronchi in the surgical treatment of pulmonary tuberculosis.

GYNECOLOGY AND OBSTETRICS

VOLUME 84

APRIL 15, 1947

NUMBER 4A

IDEALS IN SURGERY

W EDWARD GALLIE, M.D. F.A.C.S. Toronto Canada

THIRTY THREE years ago a group of very wise men founded the American College of Surgeons. It was their hope that by gathering together in such a College all the surgeons and surgical specialists who were known to be morally and ethically fit and who had demonstrated by their training and by their standing in the professional world that they were properly qualified, the standard of surgical care might be raised to the level that a great people deserves. It was hoped too that with the lapse of a few years the diploma of Fellowship in the College would become so desirable and so necessary that all who proposed to practice surgery would seek it and that by and by it would constitute a clear index whereby those who were qualified to do surgery could be distinguished from those who were not.

Since the day of its foundation the College has grown and prospered and it has done those things to a superlative degree for which its founders so fondly hoped.

As time went on, however, and the future of the College had been firmly established there arose both within it and without, a demand for a definite raising of the requirements for admission to Fellowship, both in the form of longer and better practical training and of proficiency not only in surgery but also in all the basic sciences related to it. The College recognized this demand by two modifications,

in the past eight years of the length and character of the training required. Others felt, however that all those who proposed to specialize should be forced at an early stage in their graduate training to demonstrate to a court of examiners that they were proficient in the principles of surgery and in the allied basic medical sciences. From this arose the American Board of Surgery and the boards of the various surgical specialties, to which the College elects representatives.

The aim of both the College and the Boards has been the improving of the quality of American surgery and both have been successful. The College insisted on minimum periods of apprenticeship, evidence of high moral and ethical standing, and proof that the candidate had shown ability in practice. It concerned itself with the raising of the standards of the hospitals in which its Fellows would study and work, it busied itself with advanced surgical education, as indicated by this Congress today and it is now engaged in what may prove to be its greatest effort on behalf of American surgery the establishment of adequate graduate training. The Boards have outlined more sharply the periods of hospital training that are required and have made sure by requiring the candidates to pass searching examinations, that they have an adequate knowledge not only of the art of surgery but of the basic sciences, without which no man can be a true surgeon.

Speaking now not as President of the College, but as a Canadian and a most free

Address of the retiring President, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

onlooker I recognize the same high motive in both the College and the Boards, and I see great virtue in what each has done. It seems to me however that it is a pity to have two separate roads to public recognition and that a combination of the two with adoption of what is best in each would add great strength to the crusade for higher standards and would ultimately serve the people best.

But while the setting up of standards for qualification to practice surgery is a step in the right direction it will prove quite futile if conditions are such that these standards cannot be achieved. What does it profit to tell a young graduate that he must serve a period of supervised training in an approved hospital, extending over a period of 3 or 4 years if a sufficient number of such hospitals do not exist? A survey of the hospitals of Canada has shown that only a few can at present be approved for graduate training and the same lamentable state of affairs obtains in the United States as well. Only in a few of the hospitals attached to medical schools is there any attempt at the planned training of internes and residents and in very few of these any provision for instruction in the basic sciences. How many hospitals do you know where a three year assistant residency is offered or where regular ward rounds or conferences are held or where supervised courses of study are provided in anatomy, applied physiology and applied pathological chemistry? And how many hospitals do you know where internes are encouraged to make use of the libraries or to take part in surgical research? The answer is, very few. There are of course outstanding examples to the contrary where the training of the interne is a major interest of the staff but when one adds up the number of these hospitals and makes up the grand total of the graduates receiving such training it will be found that the number is very small.

This is the reason for the present activity of the College in graduate training and for its effort to induce hospitals to make the necessary reorganization of their staffs and to adopt the resident system.

Unfortunately the reformation that the College has in mind is by no means so simple as

one might suppose. While most hospitals are interested to a certain extent, because certification by the College that a hospital is approved for graduate training would ensure a constant supply of good internes, yet many of these hospitals balk at the radical staff reorganization involved and hesitate to put the time and effort into a teaching program that could be considered adequate. It is clear that to make a success of its graduate training plan the College will require the good will of the public and the whole medical profession and the strong support of all the Fellows.

In support of the program of graduate training I propose to discuss with you briefly the plan which has been in operation in the University of Toronto for the past 18 years. I have no thought that it is adaptable to all situations nor have I any notion that it is as good as that in many of the great American universities, particularly those with sufficient endowments to enable them to grant numerous fellowships toward graduate training. It does illustrate, however, what can be done by long term planning and by persistent effort at reform.

Twenty five years ago the Toronto General Hospital (1,000 beds) staffed by the best surgeons in the land all members of the Medical Faculty had never trained a surgeon. Internes came for a year or two and departed, usually into general practice. Those who aspired to become surgeons sometimes went to New York to seek a further internship, or more often went to London or Edinburgh to study for the coveted diploma of Fellowship in one of the Royal Colleges. These Fellowships were won by passing the stiffest kind of examinations in anatomy, physiology, pathology and surgery and they were a guarantee that the successful candidate at at least one stage in his career had been familiar with what the textbooks said about them. They did not, however guarantee that the Fellow had any satisfactory apprenticeship or had become a master of his craft. It was only when he returned to his home and had received a junior hospital appointment that his practical training began.

Under this system a small group of surgeons was developed from which the medical school and the hospitals selected their staffs.

Then came the era of the building of small hospitals and with it the enormous increase in the number of surgical operations. These operations, of necessity were performed by practitioners of very little training who had learned what they knew from books from observational tours, and from the hard experience of trial and error. I know one such hospital serving a neighborhood of six or seven thousand people where the operating rooms are busy every day from nine to one and where not a single operator ever had more than a rotating internship. It was to try to force an elevation of the standards of education of these surgeons that the American College of Surgeons was founded.

Recognizing that the raising of standards was useless unless provision were made for training candidates to meet those standards the University of Toronto 18 years ago embarked on a program of graduate surgical education which gradually became standardized and which now constitutes the chief source of supply of trained surgeons for the Province of Ontario and indeed for the whole country.

The course is based on the theory that if the highest type of medical graduate is attracted to it, the best results will be obtained by combining the virtues of the apprenticeship system with those of the tutorial system. We had in mind that to ensure that the student profit most from his years of surgical residency he must be forced to undertake systematic study. To do this we arranged a definite curriculum composed both of practical training in hospital and of the instruction and study necessary to enable the candidate to face examinations for the Master's degree M.S.

The following is the minimum course

1. A rotating internship in an approved hospital with at least 6 months of general medicine
2. At least 6 months in pathology
3. One year on a general surgical ward
4. Six months in each of three surgical specialties.

At the end of this minimum course many of the candidates qualify for the M.S. and go out to practice. Others who have shown outstanding qualities and are thought worthy of Uni-

versity staff appointments here or elsewhere are selected to remain as Fellows in general surgery or in one of the surgical specialties. During this period they rank as junior members of the staff and are permitted to assume independent responsibilities.

This plan of graduate training is quite elastic. As I have outlined it, it is a minimal course which may not be shortened but which may be lengthened as circumstances seem to require. Thus for the young man whose object it is to leave the university and go into practice at a distance, we suggest that he take in addition to his general surgical training as many of the surgical specialties as possible. Six months assistant residencies in orthopedic surgery gynecology, urology and the surgery of childhood are of great value to him. On the other hand for the man who has made up his mind to devote himself to one of the specialties such as orthopedic surgery we release him from service in gynecology and urology and limit him to 6 months in neurosurgery and an extra 18 months fellowship in orthopedics.

For men who because of their scholastic attainments general aptitude, and qualities of mind are considered as possible candidates at some future date for residencies and ultimately for staff appointments, a longer course is provided. These men after their rotating internship spend one or more years in the Departments of Anatomy, Physiology, Pathological Chemistry or Pathology before finally embarking on their surgical training. Then if as assistant residents they have continued to do well they are sent abroad for a year in some active surgical center before returning for their period of residency and ultimate appointment to a Fellowship in Surgery and a junior post on the staff. Often before finally settling down to their staff appointment these men spend a year in one of the more active producing surgical laboratories, a preparation for research work when they come home.

As already mentioned this planned apprenticeship is combined with a prescribed curriculum of studies leading to the degree of master of surgery. To win this degree the candidate must pass a stiff examination in surgical anatomy and in applied physiology and pathological chemistry. Later he faces

written and clinical examinations in pathology and surgery. Finally he must present a thesis on some clinical or experimental studies conducted by himself during his years of training.

To encourage these young men to take full advantage of their opportunities the University has given them the privileges of the anatomical laboratory and has provided first class tutors. Half of the assistant residents go to the laboratory on one night a week and the other half on another. In this way they review the whole human anatomy in two years.

Similarly the Department of Physiology conducts a series of lectures and discussion groups on applied physiology and the Department of Pathology does likewise.

And finally in order that these young men may be prepared for the examination for Fellowship in one of the Colleges or for certification as specialists by one of Canadian or American Boards, a series of evening discussion groups are directed by younger members of the staff on the principles of thoracic surgery and vascular surgery, neurosurgery, urology and orthopedic surgery, which many of the assistant residents may have missed in their selection of specialties.

Such a program may appear pretty extensive and to require a great deal of organization. This is not so however for the various departments involved have shown keen interest in graduate education and are glad to have students who are in earnest in their search for knowledge. The Department of Anatomy affords a good example. In these days when the time allotted to the teaching of anatomy to undergraduates is being so reduced that none but a superman could be expected to acquire any practical knowledge of it, the department welcomes the opportunity to teach students who have the time to devote to it and who really want to know what is under the skin.

The real difficulty in inaugurating such a planned course of graduate training will be met with in the Department of Surgery itself. The idea that as members of the surgical staffs of teaching hospitals our most important duty is to train surgeons has not been appreciated by many and is an idea which requires propaganda to inculcate. The old plan of using

internes and assistant residents as servants must be abandoned if we are to get good results. Indeed I am convinced that even in many old established teaching hospitals a real birth in the ideals and aspirations of the staff will be required before real progress is made. I suggest to you that the ideal of the teaching surgeon should be not how skilful and impressive he can make himself by constant practice and repetition but how many young men he can train to be as good or better than himself. Only when such an ideal is established can we hope to supply the needs of our country.

The difficulty is that busy surgeons often find it irksome to stand on the opposite side of the table assisting a young tyro in his first difficult operations. Too often they impatiently do the operation themselves or turn the job over completely and take no further responsibility for it. This, in my opinion, is poor teaching and is clear evidence that it is time for a change in the personnel of the staff. There is, of course no excuse whatever for the old custom in which a star performer at some well known metropolitan hospital posts a list of operations for certain days in the week and does them all himself. Fortunately that sort of thing has almost passed away.

The truth is that in modern first class teaching hospitals the diagnosis should be made, the type of treatment selected and the operation performed by the resident staff under the constant guidance and supervision of their teachers. The attending staff should reserve for itself only special groups of cases on which they are conducting clinical research and those cases which obviously require more experience and skill than the assistant residents have so far acquired. These are the hospitals with huge lists of applicants and which attract the high honor graduates from near and far. Such hospitals are famous across the land for the quality of the men they produce.

But, as I have already pointed out, I feel that there should be added to this program a planned purposeful course of study leading to an examination for a higher degree and to a Fellowship in our Colleges. Such a curriculum spread over 3 or 4 years, is no hardship to the student and I feel sure that a review of the basic sciences carried out concurrently with

clinical work, and a definite program of clinical study and instruction results in a far sounder surgical education than the haphazard methods of other days.

But even with all the teaching hospitals of America supporting such a plan, not nearly enough opportunities for graduate training will be provided. To give such opportunities to the crowds of young men now demobilized from the Armed Forces and to meet the urgent needs of the country other means must be found to secure for these men the 3 or 4 years of clinical training necessary and to give them an opportunity to review the basic sciences. This is the basis of the present 'Graduate Training' campaign of the College. It is really an effort to persuade the larger non-teaching hospitals to adopt the 'resident system and certain minimum standards considered by the College and the Boards as essential to the proper training of a surgeon or surgical specialist.

If this campaign is successful it will undoubtedly overcome the present dearth of qualified surgeons. It can be successful however only if it has the overwhelming support of the Fellows and it is for this that I appeal tonight.

To make it work the hospital must have a sufficient number of public ward beds to provide an adequate service for a resident staff. The attending staff must be persuaded that in return for privileges of their appointment it is their duty to train the internes. The staff should be small and should contain one or more men who have been trained in the resident system in a teaching hospital. They must be prepared to give much time to a teaching program, much as is done in teaching hospitals, and to compensate younger members of the staff an honorarium of some sort should be provided.

In order that an assistant residency in these hospitals may qualify a candidate for admission to examination by one of the Boards or for Fellowship in the College provision must be made for instruction in the basic sciences. This calls for an arrangement with a neighboring medical school and may require a moderate expenditure to defray the expenses of the school. If the hospital is in the same town the

problem is simple but if it is at a distance it is more difficult. It can be overcome, however, as has been done in Hamilton, Ontario, where the assistant residents come 40 miles by train to spend one evening a week in the anatomical laboratory and to attend a lecture on applied physiology.

Now while I am urging that it is the plain duty of all surgeons on the staffs of public hospitals and particularly the Fellows of this College to join in this campaign I should point out that the reward for hearty co-operation in it will be great and the penalty for failure will also be great. You must all have observed that with the establishment of higher standards for qualification by the Boards and the College those hospitals known to provide approved courses of training are being so inundated with applications that they are able to fill their resident staffs with the pick of the graduating years. On the other hand those hospitals which have not been approved for graduate training or are known to provide in different courses, have very few applications and these only from graduates who are not acceptable elsewhere. The result is too obvious to require comment.

As the years have rolled along it has been interesting to observe the results of our planned course of training. Some of the graduates who have shown aptitude for teaching or research have won appointments on teaching hospitals and a few have become professors. The outstanding result, however was that when the Canadian Armed Forces needed highly qualified young surgeons they were ready and were able to give our soldiers, sailors and airmen a service that has hitherto been unsurpassed. And now with demobilization these officers are settling into civilian life and bringing to the Canadian people both in the cities and towns a quality of service of which their teachers are very proud.

This group which now has grown to seventy-five has banded itself into a club which meets once a year to spend a day at the hospital where they were trained and to enjoy a clinical program and a dinner. To this gathering are brought all the trials and difficulties of practice and it is seldom that the trouble is so great that it cannot be solved. Through it

SURGERY GYNECOLOGY AND OBSTETRICS

there has developed an excellent esprit de corps and a tradition which ensures that the general plan will long continue.

It is the opinion of this group that the young surgeon recently certificated and accepted to Fellowship in one of the colleges should limit himself entirely to surgery or his particular specialty. At first it was thought that this could not be done and that a surgical practice could only be acquired through general work. It has been shown beyond a doubt however that this is wrong and that, on the contrary it is the surest and quickest road to success. The explanation is that general practitioners are far more willing to refer surgical work to a specialist who is not in competition with them for general practice than to another general practitioner. They do it too without asking a share of the fee which is something on which to pooder.

In thinking over our experience of the past 18 years in this planned course of graduate training I commend to your consideration the following suggestions.

First. In order that the student may acquire a satisfactory knowledge of anatomy applied physiology and applied physiological chemistry he should be provided with a plan of curriculum of studies running concurrently with his apprenticeship.

Second. In order that he may be stimulated to engage in these studies earnestly and not perfunctorily he should be confronted with written and oral examinations.

Third. The awarding of a degree such as 'Master of Surgery' to candidates who have shown a practical knowledge of the basic medical sciences and who have demonstrated a

court of examiners skill in the art and science of surgery gives a stimulus to the whole course. Gradually the tradition develops that the M.S. is more than a diploma won by examination but that it is a written guarantee that the holder is known to his teachers to be thoroughly qualified to practice his profession. Because of this fact the attainment of the degree is much desired.

I have taken long to tell you the story of our efforts in Toronto. As I said earlier I have no notion that our plan is an ideal one or that better plans do not exist. At this time, however when the College is engaged in a great campaign to provide an increased supply of qualified surgeons it may be helpful to those who will be engaged in organizing and administering somewhat similar plans, to hear of the difficulties and disappointments and the triumphs of a plan that has been in operation for 18 years.

The honor of being President of this great College throughout the whole of the European and Asiatic war has been far beyond my deserts. The last Clinical Congress took place in Boston just before Pearl Harbor and you elected me to the presidency in order that you might do honor to my country which was already deeply involved in war. Thank God, as allies, we came through safely together and can now turn our minds to the urgent problems of peace. Of these none is more important than the health of the people and as far as this College is concerned, than that each one of our citizens, be he in the heart of the city of New York or on the fringes of Arctic civilization may be assured in some way or another of competent surgical care.

INTERRUPTION OF THE DEEP VEINS OF THE LOWER EXTREMITIES IN THE PREVENTION AND TREATMENT OF THROMBOSIS AND EMBOLISM

ARTHUR W ALLEN MD F.A.C.S Boston Massachusetts

IT is now well established that most pulmonary emboli arise in the deep veins of the legs. Illness parturition trauma, and surgical procedures are conducive to thrombus formation although this phenomenon may rarely occur in an ambulatory and otherwise apparently healthy individual. Infarct to the lung is frequently the first warning of the true situation and is often diagnosed and treated as coronary occlusion atelectasis pleurisy or pneumonitis. Sudden death with out warning is common and often the massive pulmonary embolus responsible is unsuspected until found at autopsy. There are some physiologic changes in the blood following trauma or illness, particularly those concerning the platelets, that must be taken into consideration regarding the cause of thrombosis. We believe however that stasis in the leg veins dependent on bed rest and muscular inactivity is in fact the chief underlying basic principle in the establishment of thrombosis.

In consideration of this problem from any point of view one must bear in mind certain established facts. There are definitely two distinct types of thrombosis in the leg veins. Homans (11) has used the terms bland or quiet thrombosis to describe a noninflammatory process producing loose clot within the vein. Ochsner and DeBakey (16) have coined the term 'phlebothrombosis' for the same condition. Both these authorities are distinguishing this type of lesion from the inflammatory thrombosis known as thrombophlebitis. The latter situation is easily diagnosed since the patient is made aware of it by pain in the leg. Associated with swelling of the extremity

and fever we have in its extreme phase phlegmasia alba dolens so commonly seen in the past following childbirth and often called by the layman milk leg. This condition is not as dangerous as bland thrombosis from the standpoint of pulmonary embolism but if allowed to run its course causes great and often permanent disability due to persistent edema and frequent ulceration.

Phlebothrombosis is often unrecognized until serious emboli have been carried to the lung or until the character of the lesion has changed into the inflammatory process of thrombophlebitis. Bimodal inspection and palpation of the legs may result in an early diagnosis. Mild swelling of the ankle dilatation of the superficial veins of the foot and minor discomfort on palpation of the calf muscles are often enough to lead to the assumption that a bland thrombus exists within the deep veins of the leg. The concomitant slight elevation of temperature pulse and respiration is reliable evidence that phlebothrombosis is present and that a small infarct has occurred. It is in this type of thrombosis that the greatest immediate danger exists. The long almost uninterrupted femoral vein may contain a complete cast of loose thrombus and if this becomes detached en masse the resultant occlusion of the pulmonary arteries is nearly always fatal.

The age of the patient appears to be the most important consideration regarding the frequency and seriousness of thrombosis of the leg veins. In our own cases (1) of thrombophlebitis only 5.7 per cent were in patients under 30 years of age 12 per cent were between 30 and 40 18.5 per cent between 40 and 50 and the peak incidence of 25.3 per cent occurred in the decade between 50 and 60. A total of 82.3 per cent were beyond the age of 40. It is apparent to us that sudden massive

Dr Allen is Chief, East Surgical Service, Massachusetts General Hospital, Boston. Lecturer in Surgery, Harvard Medical School, Boston.

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 10-12, 1946.

embolism is far more common in the aged. Although we have no definite evidence that phlebothrombosis is more prone to take place in the older age-group than is thrombophlebitis, there is a great deal to support this assumption in the analysis of the problem in our clinic. That some younger patients do have a bland type of thrombosis is evident, but the fulminating inflammatory thrombophlebitis is certainly more commonly seen in this age-group than in the older. We have observed all gradations of the disease. A considerable number of patients will develop an apparently noninflammatory thrombosis, especially if left untreated, and occasionally if treatment is carried out the condition will gradually change into thrombophlebitis. It is probable that this situation occurs more frequently in certain clinics and certain geographical locations than in others. Vasospasm may account for some of this variance since in cold damp climates it may be more constant than it is in warmer and dryer regions. The chronic upper respiratory tract infections with exacerbations during the colder months may play a rôle. Certainly our peak incidence of 32.9 per cent in the winter months as compared to 18.9 per cent in the summer seems significant.

The prevention of and the treatment of thrombosis and embolism must be considered separately. There has not been sufficient emphasis on these two distinct methods of meeting the problem. By prophylactic measures we refer to those carried out in anticipation of thrombosis in the leg veins. Treatment of the condition in any form after the establishment of the probable or obvious diagnosis of thrombosis or infarct is a different matter. Further, more patients in various age-groups or according to the character of their ailment or injury may be treated differently. It is unwise to overlook these separate categories in the management of this problem as a whole. Reports on the effectiveness of one method of treatment or prevention as applied to all patients are apt to be misleading. That methods of prevention and those of treatment must overlap is obvious.

Methods of prevention of thrombosis and embolism are numerous and all should be considered on a logical basis dependent on vary-

ing circumstances. Certain primary principles such as suitable preparation of the patient for operation, gentle surgical technique, and the prevention of stasis in the leg veins during convalescence are commonly agreed upon by all clinicians. Elevation of the foot of the bed, leg exercises, early postoperative walking are all considered useful. These measures alone have apparently reduced the over-all incidence of thrombosis and fatal embolism in postoperative cases from 1 in 333 to about 1 in 800 at the Massachusetts General Hospital (20). There are many patients, however whose type of disease, trauma, or other infirmities make it impossible to carry out such maneuvers. It seems to us that a selection of methods must be used on individual, age or disease group indications.

Our records show that patients under the age of forty are less prone to develop the complication of phlebothrombosis and that when thrombosis of any type occurs, it is less likely to be followed by a fatal embolism. These younger individuals are basically more healthy and active, and can co-operate more readily with the clinician and nursing staff in the routine measures for the prevention of venous stasis. There are, however, many conditions afflicting this age-group that are conducive to thrombus formation in leg veins and these must be evaluated and treated accordingly. All patients in this group must be carefully watched for early signs of thrombosis. If the condition manifests itself there is usually time to prevent a prolonged convalescence or the more important fatal embolus. Since 12 per cent of our cases of thrombosis and embolism occurred in patients between the ages of 30 and 40 years, it is probably better judgment to include this decade in the next age-group to be considered.

In patients between the ages of 40 and 65 years, we have carried out the usual general measures of prevention when possible and, in addition, have treated a small number (233) of suitable cases with dicoumarol postoperatively (2). In comparison with a control group of the same age and type the incidence of thrombosis and embolism was reduced 75 per cent. We did not use this drug on patients

with increased prothrombin time or in those with planned multiple operations, liver or renal disease, diabetes, arthritics taking aspirin in thoracic cases, hyperthyroidism or arteriosclerosis. Our dosage was smaller than usually recommended and was only 200 milligrams on the 2nd or 3rd postoperative day and repeated 48 hours later if the prothrombin time remained unchanged. The sensitivity to this drug in some patients as well as the lack of measurable effect on others was noted. No fatal bleeding took place in any patient treated. It is obvious to us that this drug is useful in many cases but that it should not be used without careful laboratory control. There are in this age-group many debilitated patients who should be considered in the next category especially those whose disease or infirmity makes thrombosis and embolism a common occurrence and those with definite contraindications to anticoagulant drugs must be protected by other methods.

Since the danger of phlebothrombosis with death from massive pulmonary embolism increases with the patient's age we have selected the group beyond the age of 65 for prophylactic bilateral superficial femoral vein interruption. This is done immediately distal to the profunda femoralis vein and as close to the bifurcation of the common femoral as is technically feasible. We have been so impressed by the negligible symptoms following this procedure on the normal femoral vein that we feel it should be more widely used. Up to October 1, 1946 there have been done at the Massachusetts General Hospital 458 such bilateral prophylactic femoral vein interruptions. In only one patient so treated did fatal embolism occur and in this case the vein was found at post mortem to have been divided 3 centimeters distal to the profunda. It is possible that this elderly obese woman with a large ventral hernia had thrombosis prior to the vein interruption. It is more likely however that the proximal segment of femoral vein acted as a nidus for the propagation of thrombi higher in the venous system. There was a firm thrombosis in this proximal remnant of vein at autopsy. In 5 other patients who were subjected to prophylactic femoral vein division there was a history of mild phle-

bitis in one or both legs following interruption. This occurred within 24 hours in 1 patient, and the longest interval was 6 weeks. In a comparable group of 458 patients who did not have prophylactic femoral vein interruption there were 55 cases of thromboembolic syndrome with 26 instances of fatal pulmonary embolism (Table I).

The operation should be done at the time of or within 48 hours after bed rest becomes necessary. Particular attention should be paid to this method of protection in patients with fractures near the hip joint. The danger of this complication in such cases is emphasized by Golodner and associates (10) as well as by Bauer (5). In 110 consecutive elderly patients with fractures of the hip region prophylactic femoral vein interruptions were done in our clinic. In 2 of these thrombophlebitis did occur but none died of pulmonary embolism. In the immediately preceding 110 patients of the same type 11 died of massive embolism. Two additional patients in this group died suddenly with signs and symptoms of pulmonary embolus but in these 2 the possibility of coronary occlusion was raised.

Almost as spectacular are the comparative studies on a group of thigh amputation cases. Veal (19) stressed the need for high femoral vein interruption in such patients for the prevention of pulmonary embolism several years ago. In 49 patients in this group receiving prophylactic femoral vein interruption, there were no deaths from embolism. In similar patients not so treated there were 6 who were proved at autopsy to have died from this cause. In the diabetic arteriosclerotic group having femoral vein interruption one instance of gangrene of the opposite extremity occurred. This may have been coincidental but the effect of vasospasm or even damage to the calcified arterial wall must be considered as a possibility.

We think many patients of the elderly age group can have prophylactic vein interruption prior to the main surgical procedure. It may be well to withhold it until after operations in the pelvis are completed particularly in resections of the rectum since venous bleeding in the field of operation is temporarily increased by division of the femoral veins.

Homans (12) is responsible for calling our attention to interruption of the femoral veins in the groin to prevent pulmonary infarct. With a cautious approach to this method of treatment 10 years ago we soon became convinced of certain definite facts. The operation in itself can be accomplished without harm to the patient. In no case in our institution has a patient lost his life or his limb as a result of this procedure. Most of them had no further infarct and those who did usually recovered. If the operation was done in the stage of phlebothrombosis, clots above and below the site of interruption could be removed with a carefully used glass suction tip. The amount of residual edema of the leg was dependent upon the duration of the disease. Thus in patients operated upon before thrombophlebitis began few had any swelling of the leg during convalescence. If the operation was undertaken for thrombophlebitis the earlier the procedure the shorter the duration of postoperative edema. This expected sequel to deep vein interruption was of surprisingly little significance as far as incapacity was concerned. There has been only one instance of postphlebotic ulceration in this group of patients.

Up to October 1, 1946 1518 patients have been subjected to femoral vein interruption at the Massachusetts General Hospital (Table II). Four hundred fifty-eight of these have been done on elderly or debilitated patients as a prophylactic measure before at the time of or within 72 hours after bed rest became necessary. One thousand sixty patients were treated by femoral vein interruption after thrombosis or infarcts had occurred. Less than 5 per cent of these had further infarcts after this procedure. In most instances these were of minor importance. In some of these anticoagulants were used with good effect. In

TABLE III.—INCIDENCE OF THERAPEUTIC AND PROPHYLACTIC FEMORAL VEIN INTERRUPTION IN 1518 CASES

those with pain and swelling of the leg due to a continuation of the inflammatory process of thrombophlebitis procaine lumbar sympathetic blocks were employed. In 5 patients in this group death occurred following further emboli. All of these had had one or more infarcts before femoral vein interruption and thereby had a lowered pulmonary vital capacity so that additional small emboli were sufficient to prove fatal. All but one of these 5 patients were well advanced in years and were suffering from incurable diseases. Prophylactic femoral vein interruption if it could have been carried out would have prevented these fatalities from embolism.

It is of course, impossible to determine accurately the number of deaths from embolism that would have occurred in this group of 1518 patients if femoral vein interruption had not been done (Table III). In fact, a fair proportion of the operations were undertaken on the basis of shortening the period of convalescence from thrombophlebitis with its usual disabling sequelae. The majority of them however were in patients whose age, disease, and infirmity would have allowed us to expect that a considerable percentage of them would have had subsequent lethal emboli. This opinion is based on previous experience with this cause of death in our own hospital. Although we have not convinced all members of our staff of the rationale of prophylactic femoral vein interruption there are few who would not urge the operation as soon as thrombosis was suspected and none would prefer other methods with the diagnosis definitely established.

The indications for this procedure now run about as follows: prophylactic interruptions 40 per cent, signs of thrombosis on examina-

tion of the legs 35 per cent and infarcts 25 per cent. There was a gradual change in the trend of indications up to 1945 when a more or less constant level was reached (Table IV). Not all patients who complain of a little soreness in the calf muscles are considered to have thrombosis. Many will exhibit such manifestations after exercise if closely questioned. Tenderness on pressure however should be strongly suspected. Slight swelling and dilatation of the veins of the foot are of great importance in the diagnosis. Late manifestations of the process are a positive dorsiflexion sign and definite swelling above the ankle. The concomitant slight rise in temperature, pulse and respiration is a reliable sign of phlebothrombosis and infarct. Pain in the chest is to be considered on the basis of infarct until proved otherwise. We do not believe that phlebograms are necessary to make the diagnosis. Furthermore the careful interruption of the normal femoral vein is definitely harmless. It is therefore obviously better judgment to err on the side of action than it is to lose a patient from a sudden massive embolism. These occur too frequently in a patient apparently doing well. Often these charts can be studied and a warning sign can be found that could have been recognized in ample time to protect the patient from that type of death. In some instances however there is no recorded evidence either on the chart or in the clinical notes that would lead one to suspect phlebothrombosis until proved at autopsy.

The site of deep vein interruption has interested us greatly. At one time we felt that this should be determined on the basis of the level of thrombosis. We are free to admit that the best results are obtained if the operation can be done at a level above the thrombosis. On the other hand one must take into consideration the dangers associated with such procedures. We have had so few complications and such a high percentage of successes by selecting the femoral vein just distal to the profunda femoris as the level of division that we now feel that this should be the site chosen in the routine case. Here we have a segment of the deep vein that is usually free of muscular branches. This eliminates troublesome bleeding during the isolation of the vein.

TABLE IV—INDICATIONS FOR FEMORAL VEIN INTERRUPTION—MASSACHUSETTS GENERAL HOSPITAL

	1937 to October, 1945				
	1937-1941	1941	1942	1943	1944-1945
Leg alone as first symptom	29	15	21	11	1
Chest pain as first symptom		3	3	3	
Prophylactic interruption		9	21	21	1

We did in our earlier series select the common femoral vein as the site of interruption in a considerable percentage of cases. This decision was usually based on the finding of thrombosis above the level of the superficial femoral. The occasional trapping of large quantities of blood in the leg after common femoral interruption particularly if the femoral vein itself is not completely thrombosed produces a dangerous immediate engorgement in the leg. This has been stressed by Ikemura (7) and by Homans (13) and has been observed by us. We now feel that the added risk of exposure of the short common femoral with its multiple radicals has little advantage and is attended by sequelae unwarranted in this type of interruption. If one finds the profunda femoris thrombosed at the time of superficial femoral vein interruption it is not difficult to ligate it in continuity after the main trunk below the bifurcation has been divided. The ratio of superficial femoral vein interruption to the common femoral in our series is about 4 to 1. In the future it will probably be rare instances only that the higher segment of the vein is selected as the site of division. Of the 5 deaths from further emboli after vein interruption 2 occurred after the common femoral and 3 after the superficial femoral had been divided. In only 1 of these did it appear at autopsy that the profunda femoris was probably the source of the final lethal embolus.

Homans (11) believed at one time that the common iliac vein on the side affected was the logical site for interruption under certain circumstances. This attack was supported by Fine and Starr (8) and by Bancroft (4). The approach should be used only when there is obvious long standing deep thrombosis extending well up into the iliac vein on one side.

Occasionally, in a well preserved or younger patient, it is a justifiable procedure. It has been pointed out by Homans that the colateral venous return is greater following common iliac division than it is after common femoral interruption. So frequently is it necessary to interrupt the veins on the opposite side that this difficult bilateral operation under general anesthesia seems rarely indicated. Homans (13) in a later report apparently feels that when the thrombosis is well established in the iliac veins low vena cava interruption is more logical since it can be accomplished at one operation instead of two. He further points out some of the difficulties of exposure and division of the iliac vein which can be friable and hard to manage under certain circumstances.

Ligature of the inferior vena cava has gained too much attention. Good results following this procedure have been reported by O Neil (18) Northway and Buxton (15) Gaston and Folsom (17) and by Kern and Berman (14). Linton, in our clinic, has performed this operation in 13 patients. All have survived the procedure but 3 have developed leg ulcerations afterward. Collins and associates (6) have stressed the importance of ligation of the ovarian vessels with vena cava interruption for septic thrombosis of the pelvic veins. It is our opinion that this procedure may at times be life-saving. It should be reserved, however, for patients having obvious septic infarcts from thrombosis that have originated in or extended into, the deep veins of the pelvis. Approach to the region has varied from flank to paramedian incisions. A few advocate the transperitoneal route. Linton prefers a long right paramedian incision with reflection of the peritoneum and abdominal viscera toward the left. Care must be exerted in freeing the segment for ligation since troublesome bleeding from injury of the friable lateral veins may influence the outcome.

TECHNIQUE OF OPERATION

Technique of operation in the interruption of the deep veins of the lower extremities should be carefully considered. We may have been remiss in our earlier communications on this subject (3) in stressing the simplicity of

the procedure. This was brought about by the fact that such a large percentage of our cases had been operated upon by the junior residents. We had failed to make it clear that these men had been properly instructed in the approach and the technique of the operation. Since our attention has been drawn to certain serious difficulties encountered by some surgeons who had not studied the problem beforehand we feel that the following details are worthy of emphasis.

The patient should be placed on the table with the upper part of the body slightly elevated. Although we have had no instance of infarct during the operation we believe that such might occur if negative pressure in the veins above the thrombosis was encouraged. The usual skin preparation for any emergency procedure is used. One per cent procaine without adrenalin is introduced by local infiltration. A vertical 8 centimeter incision is made from the crease of the groin distalward over the course of the deep vessels guided at the upper level by the pulsating femoral artery. The skin is carefully excluded by towels which are even more important in this region than in many others. Dissection should be parallel to the course of the vessels with as little lateral division of tissues as possible. This step allows for the retraction of most of the lymphatics since transection of them as often occurs in a transverse or an oblique incision will increase the hazard of postoperative edema and lymph drainage from the wound. The vein is more or less mesial but often almost completely beneath the femoral artery. The artery should be freed only enough to allow gentle retraction laterally. It is better not to retract the artery with rubber tubing or ligation material, since damage to a calcareous vessel with resultant thrombosis and gangrene of the leg by this method has been brought to our attention.

The segment of vein to be interrupted lies in the exact center of the wound if made according to these directions. The bifurcation of the common femoral vein can easily be determined by a bulge at the upper end of the superficial femoral. Exposure of the radial free upper 2 centimeters of the vein is sufficient. Ligatures for elevation of the vein are placed and not

tied at this time but the ends are held as hemostats. The anterior half of the vein is then divided transversely halfway between the two guy ligatures. If thrombus is present at this level, it will extrude through this opening. We clear the upper segment of vein of all clot by the use of forceps and carefully apply suction through a glass tube. After free bleeding is obtained the lower segment of vein is freed of as much thrombus as possible. Often free bleeding from the distal segment can be thus acquired. The ligatures are then tied above and below and the vein is completely divided. Transfixion ligatures are then placed on each divided end of the vein.

After irrigation of the wound with saline solution a layer closure is accomplished with fine cotton sutures. Care should be used not to leave open an obvious divided lymph vessel. Also the anterior crural nerve should be avoided during the closure. A complete change of gloves, instruments, and drapes is made for the opposite side. The bilateral operation should be adequately and safely accomplished within an hour. Dependent on previous inflammatory reaction in the vascular bundle and occasional friability of the vein the operation may take a little longer. Often in a thin subject with normal structures, the operating time is reduced to 20 minutes or less to the side.

This method has been followed by very satisfactory results. Postoperative edema is minimal in most instances. If the process is subacute and thrombophlebitis with swelling in the extremity is already present the edema lasts longer but is rarely incapacitating. There has been less than 2 per cent of wound infection in our series and most of this has been of minor importance. Lymphorrhea has rarely occurred and is transient. Patients are treated in the same manner with or without this procedure. It has not increased the hospital stay or delayed ambulation. The only complaints have come from those occasional patients who have had trauma to the anterior crural nerve and these have not been severe.

SUMMARY AND CONCLUSIONS

1. Bilateral interruption of the deep veins of the legs is a safe and adequate method of

preventing thrombosis and embolism. The procedure is particularly adaptable to elderly and debilitated patients requiring prolonged bed rest and those who have had trauma to the leg or hip region. Subsequent edema in the legs following division of the normal superficial femoral vein is negligible.

2. Treatment of phlebothrombosis by thrombectomy and interruption of the deep veins of the legs is highly satisfactory. Early diagnosis permits the division of the vein above the thrombosis at the superficial femoral site. It is rarely justifiable to perform a higher division of the venous system under any circumstances.

3. Thrombectomy and superficial femoral vein interruption is an effective method of treatment in early thrombophlebitis. Patients with continued infarcts following this procedure should have anticoagulant therapy. Those with continued pain and swelling of the extremity following femoral vein interruption should be treated by lumbar sympathectomy or procaine blocks.

4. Division of the common femoral vein is not recommended. If the profunda femoris is thrombosed at the time of superficial vein interruption this radial can be separately tied in continuity.

5. Bilateral femoral vein interruption should be done since often the fatal embolism arises in the opposite apparently normal vein.

6. The collateral venous circulation is better following common iliac interruption than it is after common femoral division. Occasionally in a definitely unilateral process extending into the pelvis in a good risk patient, the common iliac vein may be the site of choice for operation.

7. Inferior vena cava ligation should be reserved for those patients who are having repeated septic infarcts. These emboli may have originated in the pelvic veins or progressed to this area by direct extension from the leg veins. In pelvic suppurative thrombophlebitis, the ovarian or spermatic vein should be interrupted at the time of vena cava ligation.

8. There have been no deaths and no patient has lost a limb as a result of femoral vein

Interruption in 1518 patients so treated in the Massachusetts General Hospital

THE AMERICAN SURGEON, A U S

EDWARD D CHURCHILL, M D F.A.C.S Boston, Massachusetts

SHOCK

IN choosing the accomplishments of the surgeon of World War II as the subject of this first Franklin H. Martin Lecture, I realize that I have set myself a difficult task. The American Surgeon, A U S is a Rip Van Winkle, already packed off into the Catskills for a long sleep. His return to the platform may be accepted with tolerant politeness, but his experience is considered an affair of the past without reference to the immediate future. An acceptance of the challenge to present this subject means that I hold a deep conviction that there are many significant things that have not yet been said about the surgical experience of the recent war.

The nature of the shock exhibited by a wounded man has been made a matter of mystery for many years. During World War I observations on the shock of wounded soldiers showed that "the vasomotor center was efficiently at work and the heart was capable of assuming any reasonable burden placed upon it." (4) Attention then centered on the discrepancy between blood volume and the capacity of the vascular bed. A fruitless search for the "lost blood" led to the concept that the fluid portion (plasma) had been lost through the capillary wall by a generalized increase in its permeability. An assumption was made that toxic products derived from injured tissue damaged capillaries remote from the site of injury.

In the period between the wars this loss of plasma was localized more definitely to the areas that had been injured and both the assumptions of a traumatic toxemia and of a generalized change in capillary wall permeability were questioned. Observations were extended beyond the intravascular space to the interstitial fluid compartment. Certain electrolytes, sodium and chloride were found to move freely in the vascular and interstitial spaces but observed to meet an effective barrier to entering the cell. Others notably potassium, magnesium and phosphorus were admitted to cells, even though in low concentration.

The toxicity of potassium when given intravenously and the high level of potassium observed in certain instances of advanced shock led to the concept that it might represent a noxious agent. It was even referred to as a possible H-substance (19) a generic term that had been used to designate the products of tissue injury. At any rate no one considered that an actual deficit of potassium or other electrolytes within the cell might be an important component of injury.

World War II was started with the concept that plasma for the intravascular space and

The full impact of war experience on surgical theory and concept has by no means been measured. One reason, perhaps, is the preoccupation with novelties that characterizes the profession of today. No novelties emerged from the past war. There is no fancy packaging that leads the buyer to believe he can obtain something new and important. There were few, if any novel technical achievements. In fact, war tends to submerge the importance of technical details. Surgeons from all sections of the country are brought together in a common task with the result that specific techniques oftentimes taught as essentials in a parent school are recognized as unimportant details when placed against a broad perspective. The vast experience of war provides a view of surgery comparable to an aerial reconnaissance photograph in which the significance of a single bomb crater is lost in the display of the pattern as a whole.

At the risk of repeating what may be familiar material I shall point out certain aspects of surgery that have profited by the clarification that can come only from the impact of broad experience.

The First Martin Memorial Lecture of the American College of Surgeons, presented before the Clinical Congress of The American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.
Dr. Churchill is John H. Parsons Professor of Surgery, Harvard Medical School and Chief of the West Surgical Service, Massachusetts General Hospital.

sodium chloride solution for the interstitial space were therapeutic measures adequate to re-establish equilibrium in a wounded man. Experience in North Africa immediately demonstrated the inadequacy of this therapy and showed the necessity for whole blood (15). As soon as equipment could be obtained a blood bank, organized by the Theater with service troops as donors, supplied the full needs of the Mediterranean forces to the end of the war.

The loss of whole blood following wounding far surpassed that estimated at the beginning of the war and the degree of shock closely paralleled the amount of blood lost (16). The obvious explanation of why whole blood is needed rather than plasma is that replenishment of red cells maintains the required oxygen-carrying capacity. Future investigation will test the validity of certain less obvious explanations. Red cells form an appreciable portion of the mass of blood and a portion that cannot be lost into an area of trauma without actual disruption of vessel walls. The physical action of cells as a filler for the intravascular space may be significant, because it is not clear how long plasma administered in the face of a low hematocrit remains in circulation.

Again there is the problem of the electrolytes to which I have referred. Potassium appears in considerable concentration in the urine following hemorrhage (18). From what cells it is lost and by what mechanism is not clear. The specific effects of the departure of the potassium ion from cells on recovery from shock or recovery from other effects of the wound remain to be explored. Suffice it to say that potassium and also phosphorus are virtually lacking in plasma but present in large quantity in red cells.

Other considerations have led the attention of the surgeon beyond the capillary wall, across the interstitial compartment to the cell. The term *irreversible* borrowed from elementary chemistry is found in writings on shock. The issue is kept clear only if its use is restricted to the effects of shock and not extended to the condition of shock itself. Shock, defined as reduced blood volume flow, is reversed by replacement of blood volume. Selective death of organs or tissues brought about in whole or in part by shock is not reversible. It is probable

that each tissue and organ has a different threshold at which it succumbs to asphyxia. Functional impairment or complete suppression of function may appear in certain organs, for example the kidneys, and delayed death of the entire organism ensue, despite the fact that other organs have been reconstituted and the direct effects of the missile repaired. In this sense the effects of the wounding as reflected on the kidney in many cases have been irreversible—at least with our presently available modes of therapy.

In the past war replacement of lost blood reached an extraordinarily high level of effectiveness. It is certain that hundreds of injured men survived the immediate effects of wounds that under slightly less favorable circumstances would have proved fatal. Irreversible shock as such was not encountered. An appreciable number of the wounded survived, however, only to die about the tenth day with complete anuria. A chain is as strong as its weakest link. When links are strengthened where the chain has broken previously new weak spots appear simply because the chain holds to test them. The obvious weak link in the severely wounded in this war was the kidney.

Death from suppression of urine attracted attention for two obvious reasons. First, the syndrome is readily recognized provided the urinary output is observed; second, the time of death is quite remote from the immediate sequelae of the wounding. When the chain breaks within the first 48 hours of wounding it is oftentimes impossible to tell which of many links gave way first. Thus it is entirely possible, indeed there is evidence to indicate, that other organs may be mortally damaged by the indirect effects of trauma. The liver and the adrenal cortex come to mind as organs that deserve careful study in this respect. Any specific effects of the functional suppression of these organs are so likely to be obscured by the whirlwind of events in the first 48 hours after severe wounding that clinical observations still remain inexact and fragmentary.

At one time in World War II there was a trend which, if allowed to develop might well have separated the treatment of shock from surgery. The following is an extract from an

official report of the Surgical Consultant,
North American Theater of Operations dated 2
July 1943

Hospitals receiving battle casualties from the
field establish a Resuscitation Ward to which pa-
tients requiring resuscitation are sent from the Re-
ception Ward. A Resuscitation Team of Medical
Officers is constantly on duty. This is an efficient
arrangement and absolutely essential when casual-
ties arrive in overwhelming numbers. There is one
drawback which if clearly recognized may be
guarded against. Resuscitation comes to be regarded
as a subspecialty of military surgery and as such be-
comes a goal in itself. One central fact must be kept
in mind and although it appears obvious it is often
overlooked both in theory and practice. *A wounded
man is resuscitated not only to save life but to prepare
him for necessary surgery.* Starting from this axiom
a number of principles become clear.

(1) Any delay in resuscitation prolongs the cru-
cial interval between time of injury and operative
treatment. Also delay in the reversal of shock in-
creases the deleterious effects of circulatory failure.
Delays in resuscitation procedures have been ob-
served that were attributable to

(a) Insufficient grasp of these fundamental prin-
ciples chiefly on the part of junior grade ward offi-
cers with inadequate training in surgery. This is of
course a reflection on

(b) Failure of the operating surgeons to follow
closely the clinical course of patients in the Resusci-
tation Ward. They wait for them to be served up
to them. This divorce of surgeon from shock is a dis-
quieting outgrowth of the war that cannot be too
strongly condemned. Resuscitation in every case be-
fore prepared for operation is an integral part of the
surgical management of trauma and must remain so
if optimal results are to be achieved.

In the Italian Campaign Dr Henry K.
Beecher made many important observations
both clinical and quantitative, on the prepa-
ration of the wounded for surgery and pre-
sented a broad definition of resuscitation
that includes operation as an essential com-
ponent.

"The enemy has produced the worst wound he
could and its consequences are cumulative—de-
hydration increased by unusual fluid loss in sweat
and vomitus, continuing hemorrhage or plasma loss,
pain making rest impossible, increasing emotional
exhaustion, developing infection—these and other
factors are set in operation by the initial wound
They progress in the seriously wounded to be checked
ed in most cases only by surgery or by death. Resusci-
tative measures give a temporary stay and make
successful surgery possible in the severely wounded
but in most cases true release from the consequences
of the wound is effected only by surgery. Surgery is

not only the goal but is itself a part of resuscitation
in the broad sense. Any other view is likely to lead
to unfortunate separation between the activities of
the shock team and those of the surgical team.
Care of the wounded man must be continuous and
supervision uninterrupted (2)

This point of view, developed during the
war has a direct bearing on such practical
matters as the design and placement of sur-
gical hospitals. Converging litter carries and
ambulance shuttles come to a junction at the
Clearing Station of the Division. Here casual-
ties are sorted and their disposition deter-
mined. During the campaign in Sicily (6) it
was determined that the surgical hospital for
treatment of the severely wounded should be
placed alongside of the Clearing Station so
that a short litter carry would place the casu-
alty in the hands of a competent surgical team
equipped not only for resuscitation in the nar-
row sense but for the major procedures of sur-
gery. One reason for this location of the hos-
pital was to avoid the holding of a seriously
wounded patient in a station not equipped for
surgery while futile efforts were made by the
infusion of plasma or blood to prepare him for
another ambulance lift, even though it were a
short one.

Upon entering the surgical hospital the
wounded man's response to blood replace-
ment therapy was carefully observed. If the
response was transient or unsatisfactory par-
ticularly in the case of an abdominal wound
it was assumed that either continuing hem-
orrhage or spreading infection was present
and operation was immediately undertaken.
By this aggressive course many lives were
saved.

To clarify thinking resuscitative measures
carried out in the field, forward of a surgical
hospital were considered as temporary and
designed only to preserve life during trans-
portation. They thus became both qualita-
tively and quantitatively different from those
combined with surgery. It was necessary to
rely on plasma as the chief measure to support
the patient during transport but this was used
in minimal amounts without intent to restore
the volume flow to a normal level. Resuscita-
tion within the hospital included additional
plasma, whole blood, initial wound surgery

and ancillary measures such as bronchoscopy oxygen therapy and nerve block to relieve pain.

The resuscitation of severely wounded soldiers provides a lesson pertinent to the management of the victims of civilian accidents. In transportation to a hospital equipped for major surgery only such delay should be countenanced as is essential to deliver the patient to the hospital alive. Similarly hospitals likely to receive such patients must be organized so that there can be no delay in the institution of the resuscitative measures that must carry the patient to the operating room and through the essential life-saving surgical procedures.

What has been called the pathology of shock (Moon) that is the microscopic changes in the tissues that are attributable to shock, has long been a matter of discussion and confusion. Blalock succinctly stated:

The length of time that the patient lives with an inadequate supply of blood and oxygen to the tissues determines the alterations that are to be found in them. (3) Again Yandell Henderson remarked that unless one is burned alive, the tissues of one's body always die of asphyxia. (10) It is apparent that postmortem studies must distinguish between those changes that are common to death from whatever cause and those changes that result from the exposure of the tissues to the insult of a period of reduced blood volume flow. Such a beginning has been made on the basis of war material by Dr. Tracy Mallory (13) and it may be expected that another area of confusion in the so-called shock problem will be resolved, at least in part, by the establishment of the pathology of shock as contrasted with the morbid anatomy of death.

WOUND INFECTION

The subject of wound infection is so closely linked with the surgical management of wounds that it will be dealt with briefly. Only rarely does anaerobic infection complicate the injuries of civil life yet it may reach almost epidemic proportions in war. The predominance of bullet wounds over high-explosive shell wounds until the year 1914 tended to keep the incidence of gas gangrene low then

came the catastrophic experience of the British Expeditionary Force in France and Flanders. The striking reduction in the incidence of gas gangrene in the latter periods of World War I proved, as Archibald states:

The incidence of gas gangrene can be taken as the one reliable yardstick by which to measure improvements in field evacuation and in forward surgery. (1)

Taking up the subject during the campaign in the Western Desert, Major J. D. MacLennan (12) of the Royal Army Medical Corps clarified the approach to anaerobic infections for the surgeons of World War II. He attacked the widespread impression that the anaerobes constitute a small and highly dangerous group of organisms rarely found, difficult to grow and productive only of spores, bad smells, tetanus, and gas gangrene. He showed, further, that the absence of anaerobic bacteria from war wounds is a "matter for surprise rather than satisfaction, their presence for resignation rather than alarm." MacLennan's emphasis on the fact that anaerobic infections are clinical, not bacteriologic, entities provided the substance for a vigorous educational campaign. Setting up the entity of *anaerobic cellulitis* as distinguished from *clostridial myositis* brought clarity of definition and an understanding of anaerobic infection to hundreds of surgeons upon whom rested the responsibilities for preservation of life and limbs. That this concept needs emphasis in civilian teaching and the civilian practice of the surgery of trauma is immediately apparent to surgeons returned from the war.

It is difficult now to recapture the confusion in the prevailing doctrines regarding sulfonamide prophylaxis and therapy that was cured over from civilian surgery to military surgery at the time of Pearl Harbor. War experience completely unseated the dangerous teaching that wounds could be salted down with sulfa drugs as an alternative to prompt surgical treatment. The civilian surgeon entered World War II obsessed with the efficacy of the topical application of the sulfonamides in the prophylaxis of wound infection. He returned from war with faith in the therapeutic use of penicillin and at times, sulfadiazine, adma-

tered systemically to control impending or established invasive infection¹

The ability to check invasive infection by hemotherapy freed the surgeon from inhibitions that long have stayed his hand. The fear of fanning the fires of infection by the surgical manipulation of infected tissues following trauma was banished. A bold revolution in the management of wounds took place. This has led to changes in the basic concept of the surgical approach to wounds and traumatic injuries.

REPARATIVE SURGERY

By the acceptance of the term "reparative surgery" in a War Department Technical Bulletin (TB MED 147, March, 1945), the Surgical Consultants Division of the Office of The Surgeon General gave official recognition to a concept of wound management that originated in the Mediterranean Theater of Operations. The validity of the concept was strengthened by subsequent experience in the field. The cessation of combat in northern Italy found it firmly established among the surgeons of the Theater.

This phase of wound surgery follows the débridement or initial wound surgery established as a basic procedure in World War I and perpetuated in the recent war as the key stone of wound management. Reparative surgery has been described as follows: "A highly significant and far reaching advance in military surgery has taken place in the base hospitals with the development of what may be called reparative surgery. Wounds left unsutured at the initial operation are routinely closed by suture usually at the time of the first dressing. With the use of penicillin as a safeguard against infection, the management of wounds complicated by fracture or joint involvement has been revolutionized. Surgical procedures in special fields of surgery—thoracic,

cranio-cerebral, abdominal—have also been radically altered by the application of similar principles. The significance of this development and its effect on returning an increased number of wounded soldiers to duty and in preventing deformity, disability, and death in the seriously wounded can hardly be overestimated.

"Reparative surgery is not to be confused with the reconstructive surgery of the Zone of the Interior. Reparative surgery is designed to prevent or cut short wound infection either before it is established or at the period of its inception. Once established wound infection is destructive of tissue and at times of life. In many instances it permanently precludes the restoration of function by the most skillful reconstructive efforts.

"If the initial wound operation has been a complete one, wounds of the soft parts may be closed by suture on or after the fourth day. The dressing applied in the evacuation hospital is removed under aseptic precautions in an operating room of a general hospital at the base. Following closure, the part is immobilized preferably by a light plaster encasement, or if this is impractical, by bed rest" (5).

A parallel evolution in wound management, differing only in unimportant details, took place in the Central Mediterranean Forces of our allies, with whom a close and cordial professional relationship was enjoyed from the time of the invasion of North Africa. Brigadier Harold C. Edwards (9) Consulting Surgeon A.F.H.Q. in a Report to the Director of Medical Services covering the period March 1 to October 31, 1944 referred to the subject as follows: "It is not too much to claim that the surgery of war wounds has undergone a radical change since the first mass experiment in delayed suture was planned before the battle of Cassino.

'The accepted treatment of all wounds is a two stage operation' irrespective of whether an open fracture exists or not. This conception has led to an immense diminution in invalidism as a result of chronic sepsis of pain and discomfort, and of numbers of dressings. It has led to an incalculable saving of hospital beds (one analysis has showed the saving to be

Italics by the writer

¹That deep instinct of the surgeon to anoint the wound with healing balms, salves or antiseptics and to keep it open with sponges, tents or tubes, finds its roots in the mysticism and polypharmacy of the ancients. It still plagues our craft in the usage of the precise tools of chemotherapy and antibiotic agents. A long line of illustrious surgeons, basing their experience more often than not on the battlefield, have combatted the doctrine that the healing of a wound is governed by the topical applications of the surgeon. This line of dissent extends from Lord Monaghan, the great septic of World War I, through Lister, Wurtz, Park, Henry of Mondeville, Hugh of Lucca and Theodoric, Celsus, and the Good Samaritan, to Hippocrates.

as 24-35) and in consequence of manpower Men are fighting now¹ who have already twice recovered from wounds since the 'D Day for Cassino—May 12th. Furthermore the result ing scars have been firmer less adherent and less liable to break down.

In the Royal Army Medical Corps the terms delayed suture and secondary suture were retained and the program as a whole referred to as the treatment of a wound by a two-stage operation.

The adjective *reparative* was chosen by the U S Army Medical Corps to set apart the phase of surgery under discussion from the initial operation (debridement) that precedes it and the reconstructive surgery that may follow. Reparative surgery has been referred to as surgery of necessity for a limited time exists following the initial surgery during which its maximum benefits may be secured. It is neither emergency surgery on the one hand, nor elective surgery in the sense that it may be postponed, on the other. The word *reparative* was chosen with reference to the technical procedures that repair damaged and distorted anatomic parts also it indicates that the surgery coincides with the period of greatest biologic activity in wound repair. This starts on the fourth day the time selected on purely clinical grounds as the optimal time for surgical repair of a soft tissue wound. There is no sharp end point, but for the simple wound the optimal phase for surgery closes at approximately the tenth day. This time interval for reparative surgery is fixed by biologic laws to which military planning must accede unless grim necessity demands sacrifice of that part of the potential combat strength of the force evacuated as lightly wounded.

The application of the procedures of reparative surgery requires an analysis of a wound in terms of the structures that have been damaged for the repair of each tissue and structure is subject to different laws. It also stimulates a precise analysis and recast of terminology to achieve uniformity in definition and clarity in thinking.

It is important that the scope of the term *reparative surgery* be clearly understood. It is by no means synonymous with delayed

primary suture, delayed suture, and secondary suture." Reparative surgery defines a phase of wound management during which these procedures, referred to as the second stage of the two-stage operation by Edwards are carried out. In addition, other operations such as decortication of the lung, the early removal of foreign bodies, the repair of nerve injuries, and the final reduction of battle fractures are considered as reparative surgery because they are designed to prevent or cut short wound infection either before it is established or at the period of its inception or concerned with restoration of the function of its part by anatomic repair.

Wounds are referred to as simple² or soft tissue wounds when the injury is confined to skin subcutaneous tissue and fascia and muscle damage is not extensive. A complex³ wound has, in addition to the soft tissue wound, damage to nerve, bone, tendon, joint or major vascular trunk, or extensive damage to muscle that will materially interfere with function. In the management of a complex wound subsequent to the initial surgical debridement, separate consideration must be accorded each component part of the wound, such as the wound of the soft tissue, the wound of the bone or that of the nerve. The timing the sequence and the extent of the reparative surgical procedures carried out on a complex wound are determined by its component parts their extent and nature, and the wide variety of combinations in which they may be present.

Thus the term *reparative surgery* designates a phase of wound surgery applicable to complex wounds as well as simple wounds.

¹The term "simple gunshot wound" was defined and used by N. J. Guthrie in recording the opinions and practice of the Medical Department of the British Army at the termination of the Wars in Spain, Portugal, France, and the Netherlands in this and his. Simple wounds were "wounds in Parts of the body in portance or Comparative Consequence to the Human Frame."

²Various terms have been used to describe wounds that are more extensive than simple wounds. The adjective "compound" is closely linked by usage with open injuries of bone and joint and has thereby acquired specialized significance. The term "compound" implies complications such as secondary hemorrhage or infection and for this reason is best reserved for wounds with sequential pathologic entity. Also, "compound" means fracture of bone and joint surgery and "compound" fracture is one with adjacent injury to other structures such as nerve or joint. In the sense used here, *complex wound* is one with multiple and important anatomic components that are interests of the past.

³The report is dated 6 December 1944.

rather than any single technical procedure such as delayed suture of the soft tissues. It includes a wide variety of operative procedures for complex wounds as well as closure of the skin and underlying soft tissue. Also as a comprehensive term it includes a number of methods of closure of simple wounds that find a constant application when large numbers of casualties are being treated. The terms 'delayed primary suture' and 'secondary suture' describe the closure of the skin in terms of the time interval that has elapsed before closure is attempted. Universal agreement is lacking as to the actual time intervals that are implied by the use of these two terms and experience has shown that, after all, no sharp line exists so far as the ultimate result is concerned provided the surgical technique employed is adapted to the specific problem at hand. For this reason the inclusive term 'reparative suture' has come into use implying a delay and contrasting with primary suture.

In general the following principles will be found valid in the management of a simple wound or the soft tissue component of a complex wound.

1 When the initial surgery (débridement) has been complete and the wound has been protected from subsequent contamination by an occlusive dressing and adequate splinting the optimal time for closure is the fourth post-operative day. At this time muscles and fascial planes may be sutured with catgut, cotton or silk, and closure of the skin defect may be aided by the advancement or rotation of flaps or the application of a split thickness graft.

2 As the time interval is increased beyond the fourth day, the feasibility of anatomic layer closure diminishes and there is a steadily increasing number of cases in which closure must be performed by single sutures passing through all layers.

3 On or about the tenth day it will be found necessary to undercut the cutaneous margins, with or without the removal of surface granulation tissue to obtain skin approximation. The incidence of kindly healing will be appreciably lessened and the ultimate scar will tend to spread.

4 Again as the time interval is extended beyond the fourth day there will be found an

increasing indication completely to excise the wound before suture thus to restore flexibility and permit layer closure. This procedure is limited to wounds in anatomic regions where additional loss of tissue will not interfere with the ultimate functional or esthetic result. In very late wounds (3 weeks to 6 months) complete wound excision is an essential prelude to closure by suture and may be necessary or advisable preceding skin grafting.

5 When the initial surgery (débridement) has not been complete and devitalized tissue remains in the wound a purulent exudate at times associated with a foul odor will be apparent by the fourth day. Under these circumstances the residual necrotic tissue may be excised and the wound closed immediately or following excision the wound again may be left open and closure undertaken when it is certain that all dead tissue has been removed and invasive infection is not to be reckoned with.

6 When invasive infection is present, free drainage is established and tissue devitalized by the infection or by the original trauma is excised. The interval before closure may be attempted varies with the severity and extent of the infection but usually falls within the 10 day period following the operation.

Management of the soft tissue component of a complex wound is modified by the treatment that must be directed to those injured structures that are important to the ultimate function of the part. In a complex wound the goal of reparative surgery is not limited to the closure of the soft tissues and skin but extends to the repair of the wound of the bone, the nerve or the important muscles that have been divided. In general early closure of the skin is greatly desired to exclude further bacterial contamination but it may be delayed deliberately. For example following reparative suture of a transversely divided quadriceps femoris or deltoid muscle the skin may be left unsutured in selected cases to provide free escape for blood and wound exudate. Skin closure is then carried out in approximately 4 days. Battle fractures are complex wounds and usually the most important component of the wound is the fracture rather than the soft tissue defect. After accurate re

duction is secured closure of the muscles over the fracture site is the most vital step of reparative surgery. Suture of the skin may be delayed, or if the defect is small, spontaneous healing may be anticipated long before the fracture is united. Again complete or partial division of a nerve may be the most important component of a wound. Here the first step may be complete suture of the soft tissues and skin to obtain clean healing with minimal scar formation. Repair of the nerve then may be undertaken at a 3 week interval. When nerve and bone are both injured still more elaborately staged procedures may be indicated, always with the goal of the restoration of the ultimate function of the extremity in mind.

The surgical principle that has emerged may be summarized as follows. Following an open traumatic injury excision of dead and devitalized tissues should be done at the earliest opportunity. This may be considered as an initial operation and care is taken to conserve all viable parts that are important to subsequent function. Dressings and splinting are designed to minimize swelling and prevent further damage to structures by motion. Invasive infection is held in check by systemic chemotherapy. The patient may then be transported to receive the full benefit of whatever specialized technical skills are required for the reparative surgery of complex injuries. The application of this principle in civilian trauma is readily apparent.

THE PATTERN OF TRAUMA

The war experience with traumatic injury emphasizes the need for further understanding of what may be called the pattern of trauma. When individuals are simultaneously subjected to trauma or sequentially exposed to the same trauma, the resulting injuries conform to a type pattern. This has long been recognized in civilian injuries, and entities such as miner's elbow and bumper fracture are surgical classics. It is a familiar finding in disasters and I need only mention the Cleveland Clinic fire and the Boston Coconut Grove fire to emphasize the necessity for immediate recognition of the pattern of trauma. There were similar incidents during the war such as the Bari air raid and of course most

notably the atomic bomb attacks on Hiroshima and Nagasaki. Recognition of the pattern of trauma must be prompt in disaster to point the way toward effective treatment of the survivors. A recurring pattern in injuries sustained sequentially under similar circumstances leads the surgeon to propose preventive measures.

PREVENTIVE SURGERY

World War II witnessed a rudimentary but clear appreciation of preventive surgery as undeveloped phase of our craft. Preliminary explorations were made in the use of protective armor against flying missiles. Protective body armor in the form of a "flak suit" was adopted early by the Air Force. Careful analyses on the lethality of weapons and the distribution of wounds document the assertion by DeBakey (8) that the application of existing knowledge on body armor might "reasonably be expected to reduce the number of those killed in action by 12 per cent and of those wounded in action by 8 per cent. Although the war ended before body armor could be used in any area of land combat, other protective devices, in addition to the familiar steel helmet, were introduced by surgeons. Sir Alexander Hood (11) points out that the familiar crash helmet of the British Army was designed by a neurosurgeon (Hugh Cairns). Surgeons of the European Theater of Operations (7) assisted the medical service of the Air Force in a vigorous effort to prevent high altitude frostbite. With protective equipment and procedures this crippling injury of expert bomber crews was virtually eliminated. Ophthalmologists conducted extensive field studies on the use of shields designed to protect the eyes from the hazards of land mine and booby trap explosions.

The control and prevention of blast injuries of the ears were effected by joint study of Ordnance and the National Research Council. The incidence of aero-otitis, a common disability that grounded highly trained air crews was greatly reduced by control measures. Footgear effective in the prevention of trench foot was developed through Medical Department liaison with the Quartermaster. Tetanus, an ancient scourge of the battlefield, was vir-

tually eliminated by the inoculation with toxoid.

It is clear that this preventive phase of surgery must be developed with vigor and imagination to keep pace with the traumatic hazards of modern life or surgery will remain solely a salvage service. Although the surgeon is historically the senior practitioner of the battlefield, his place of importance has been yielded to the expert in preventive medicine in the conflict of mass armies. With the awful increase in the lethality of weapons and the destruction of the civilian population as the strategic objective of the enemy, it seems unlikely that military surgery will ever regain its ancient position by virtue of its salvage func-

tion alone. As the military power of this country depends upon highly specialized personnel operating extremely complicated weapons and machines, the military surgeon of the future must be an expert in the prevention of traumatic injury in addition to its alleviation.

THE DOCTOR AT WAR

Having discussed certain ways in which his war experience may have modified surgical theory and concept, I shall deal briefly with broader phases of the experience of the American Surgeon A. U. S. Pearl Harbor found the civilian medical profession in a maze of poorly integrated but highly developed specialism in remedial medicine. The prevailing tactical

There were many lessons of the first World War that were promptly forgotten or the significance of which at the time were really not appreciated. In looking back at the experience of World War I with the perspective of the recent war there is no single item that has more profound significance than the position occupied by Franklin H. Martin as the representative of the medical profession during the first conflict. It contrasts with the lack of a medical statesman at that level in World War II. On October 11, 1916, President Woodrow Wilson appointed Franklin H. Martin to the Advisory Commission of The Council Of National Defense. The story is graphically told by the pen of Dr. Martin (17) himself in his *Digest of the Proceedings of the Council of National Defense during the World War*. Representation of the profession in an advisory capacity at the Cabinet level insured that the voice of Medicine could be heard.

In this respect I would be remiss not to pay sincere and deserved tribute to our own Dr. Fred W. Rankin. Without the strategic advantage of position granted to Dr. Martin in World War I it was inevitable that General Rankin's well designed efforts should meet with frustration time and time again. Nevertheless, by skillful and untiring efforts as Chief Surgical Consultant he stands out as the Sponsor of the American Surgeon A U S and the corner

stone upon which the achievements of American Surgery in World War II were erected.

			Undetermined	1	4.3

death in only 2 instances in the patients treated with sulfonamides. There is also evidence that systemic sulfadiazine therapy has had a similar beneficial effect in operations for resection of the bowel by greatly reducing the incidence of postoperative peritonitis.

THERAPEUSIS

The value of sulfonamide therapy has been unquestionably established in acute infections produced by a hemolytic streptococcus the pneumococcus and the gonococcus but it is of little or no value in those caused by the hemolytic staphylococcus (2, 4, 12, 13, 18). Its advantages of low cost, ease of administration and high bacteriostatic action often make it the drug of choice in these infections.

Sulfadiazine is still a valuable drug in certain mixed infections produced by various gram negative and gram positive bacteria of the intestinal tract. *In vitro* studies on examples of mixed bacterial floras show that its marked bacteriostatic action is usually superior to that of penicillin in the usual concentrations which are built up in the blood during systemic therapy (Fig. 1). Clinical experience has likewise demonstrated the effectiveness of this form of chemotherapy in mixed infections. More recently very large doses of penicillin have proved to be very effective in the management of mixed infections. However certain limitations of sulfonamide therapy have become increasingly apparent including (1) the presence of bacterial species and group resistance (2) the inactivation of bacterio-

Fig. 1. static activity by inhibitors found in pus wound exudates and necrotic tissue (3) the development of drug fastness by many of the infecting bacteria (4) the occurrence of some toxic reactions when its administration was not carefully controlled (5) its inability to penetrate areas of pus and necrosis and (6) the occasional occurrence of drug idiosyncrasy.

With the introduction of penicillin many of these limitations have been overcome. The sulfonamide inhibitors have little or no effect on the bacteriostatic action of penicillin and its extremely low toxicity has been of equal significance. Doses of one million units every 3 hours have been used repeatedly and in one instance a child received 100,000,000 units each 24 hours for 2 weeks without evidence of toxicity (13). The toxic reactions that have occurred during penicillin therapy have been due largely to impurities or idiosyncrasies and the threshold of toxicity as yet is undetermined.

At the present time penicillin is the most effective chemotherapeutic agent available for the treatment of many surgical infections particularly those caused by the staphylococci, the aerobic streptococci, the gonococci and the anaerobic streptococci. Evidence of its superiority over the various sulfonamides in the therapy of staphylococcal infections is overwhelming and its effectiveness in infections caused by sulfonamide-resistant strains of the streptococcus and gonococcus have been outstanding. The micro-organisms sensitive to its action *in vitro* are listed in Table II and

those resistant in Table III. More recently the very low toxicity of penicillin has permitted exploration of the clinical value of very large doses in infections produced by bacteria resistant or slightly susceptible to its action. The encouraging results obtained justify a more thorough investigation of the therapeutic possibilities of large doses up to one million or more units every 3 hours in this type of infection.

In the 4 years between November 1942 and November 1946 704 surgical infections treated with penicillin surgery when indicated and the general and local supportive measures for correction of altered physiology have been studied and they included the following:

Staphylococcal infections	47
Pneumococcal infections	70
Anaerobic streptococcal infections	80
Aerobic streptococcal infections	46
Gonococcal infections	7
Actinomycotic infections	9
Human bit infections	8
Ratbite fever infections	
Gas gangrene infections	
Pyoderma gangrenosa infections	4

Experience has shown that penicillin is the chemotherapeutic agent of choice in the treatment of all staphylococcal infections in surgery having replaced all previous forms of chemotherapy. An arbitrary tabulation of the clinical results obtained with penicillin in the treatment of the 427 cases with established staphylococcal infections is given in Table IV.

Fig 3 J S, aged 11 years acute hematogenous osteomyelitis of right tibia with bacteremia. The chart illustrates the usual type of response of an invasive staphylococcal infection with bacteremia when diagnosed and treated early before the development of metastatic complications.

was made late however the invasive qualities of the infection were overcome and the process was localized but necrosis of tissue usually occurred. Frequently penicillin so controlled the invasive qualities of staphylococcal infections that emergency radical surgical decompensation or excision of infected areas often was eliminated or replaced by more conservative local types of surgery.

Early diagnosis was of considerable importance in determining the results obtained with penicillin chemotherapy in regard to morbidity mortality and functional results. Accurate or complete clinical as well as bacteriological diagnosis was likewise of definite importance. The presence of secondary or metastatic infectious complications usually delayed or prevented the complete response to chemotherapy (Fig 3). Failures were associated with infections in the aged, severe conditions produced by penicillin fast staphylococci overwhelming infections in patients moribund before the start of penicillin incomplete diagnosis, or the presence of endocarditis.

A more accurate impression of the value and limitations of penicillin in the management of staphylococcal surgical infections can be ob-

tained from an analysis of its effect on staphylococcal septicemia, carbuncles acute hematogenous osteomyelitis, chronic osteomyelitis, and acute postoperative parotitis.

Staphylococcal septicemia The intelligent use of penicillin has significantly reduced the high mortality and prolonged morbidity of staphylococcal septicemia. In the past the circulating bacteria were filtered out of the blood by the reticuloendothelial system and subsequently often produced secondary or tertiary metastases in the viscera even when surgical attack removed or seemed to control the primary distributing focus. Because the metastatic abscesses were frequently multiple and often inaccessible to surgery the patients surviving the initial primary infection frequently succumbed to the later infectious complications. For these reasons and our lack of any method of controlling the staphylococcus in remote or unknown areas, the mortality of established staphylococcal septicemia was very high varying between 60 and 90 per cent in various series and averaging 79 per cent. When the infection spread to the meninges or became engrafted upon heart valves, the mortality approached 100 per cent.

TABLE V — STAPHYLOCOCCAL SEPTICEMIA

	40 Cases treated with sulfadiazine, bacteri- ophage, etc. 1940-1943 Per cent	40 Cases treated with penicillin 1943-1946 Per cent
Mortality	67.5	30
Recovery	32.5	70.0
	Hospital days	Morbidity Hospital days
Fatal Cases	18	22.5
Recovered Cases	80	53.8

The obvious values and limitations of penicillin therapy in the management of this condition are illustrated in a recent study of 90 cases of hemolytic staphylococcus septicemia at the Cincinnati General and neighboring hospitals between 1940 and 1946. A total of 40 cases of staphylococcus septicemia were treated with sulfonamides, surgery when indicated or bacteriophage between 1940 and 1943 and a similar series of 50 cases were treated with penicillin in addition to other medical and surgical medical measures between 1943 and 1946. Table V compares the two series in respect to mortality and morbidity indicating the profound effect penicillin has had upon this infection.

It is apparent that penicillin has approximately reversed the mortality and recovery rates. Whereas only 32.5 per cent recovered under sulfonamide bacteriophage and other forms of therapy 70 per cent recovered under penicillin therapy. A further analysis of the fatal cases reveals some of the limitations of penicillin therapy (Table VI).

The results in the cases developing vegetative endocarditis particularly early in the series were very poor and this condition accounted for almost half of the deaths. Of the remaining 8 fatal cases, 5 of the deaths occurred within 12 to 48 hours after their admission to the hospital and start of penicillin treatment. In these instances, the fulminating infection or moribund condition of the patient produced death before the maximum chemotherapeutic effect could become manifest. In the case of the infected burn the Staphylococcus aureus was resistant to the action of penicillin.

The outcome in the individual case was dependent upon many factors (2-12) including the age of the patient, the susceptibility of the strain of staphylococcus to penicillin, the site

and nature of the primary infection, the duration of the bacteriemia, the presence and location of secondary or metastatic abscesses, the accessibility of the primary or secondary infections to surgical drainage, and the presence of other associated and complicating diseases. Inadequate treatment predisposed to relapse. Experience has shown that treatment is most successful in young adults or children in whom the diagnosis of staphylococcal bacteremia is made early, penicillin therapy given early and intensively and surgical drainage is possible when indicated.

Carbuncles. A carbuncle is essentially a spreading and necrotizing staphylococcal infection of the deeper layers of the skin and subcutaneous tissue which may result in extensive necrosis, sloughing, liquefaction of the subcutaneous tissue, septicemia, and death. The many forms of treatment which have been devised for carbuncles are an indication of our inability to control the locally or generally invasive characteristics of this infection. The great majority of surgeons have learned to employ crucial incisions or excision and because of the tendency of carbuncles to extend locally or invade the general circulation, the treatment of choice at many clinics, including the Cincinnati General Hospital, has been radical excision. Sulfonamide therapy in general has been disappointing due principally to the natural resistance of the hemolytic Staphylococcus aureus.

The marked effect of penicillin on the management of carbuncles is shown in a group of 40 cases with carbuncle which we have treated with penicillin between February 1944 and October 1946. 8 of which received both penicillin and sulfadiazine. The dosage employed was 15,000 to 20,000 units every 3 hours given intramuscularly in every instance but one in which it was given intravenously. The average

Fig. 3. J. B. aged 8 years acute hematogenous osteomyelitis with bacteriemia and metastatic pericarditis. Chart shows failure of response to penicillin therapy until metastatic infectious complication in the form of a pericarditis is recognized and treated as indicated.

total dose was 927 000 units and the average duration was 7 days.

The results of treatment indicate that penicillin is obviously the chemotherapeutic agent of choice in this type of infection. When given early in sufficient amounts and over a long enough period of time it brought the general and local invasive manifestations under control within a period of 48 to 72 hours and so modified the subsequent course that both mortality and morbidity were reduced. In our experience penicillin therapy was followed by complete and spontaneous resolution in 26.5 per cent of the cases (Figs. 4 and 5) by partial resolution with centralized necrosis in 22.4 per cent of the cases with partial resolution and abscess formation in 49.0 per cent of the cases, and by failure in 2 per cent of the cases. Thus it was not necessary to subject these patients to emergency total excision of the lesion in

order to control this infection. Since the invasive qualities have been controlled so effectively with penicillin more limited surgical procedures are recommended when indicated consisting of incision and drainage of abscesses occurring during therapy and cruciate incision for the removal of necrotic tissue.

Acute hematogenous osteomyelitis. In the past the results of treatment in this condition have been unsatisfactory for several reasons. Difficulties in diagnosis often resulted in delay and spread of the process with extensive destruction of the bone. When early diagnosis

2. Partial resolution with necrosis	11	22.4
3. Abscess formation	24	49.0
4. Failure	1	2.0

Fig. 4. F. H. aged 43 years, admitted to Cincinnati General Hospital, August 1944 with a large carbuncle of the neck of 10 days duration. Temperature and pulse remained normal after the third day. a, left, Appearance of carbuncle on August 3, 1944. b, start of treatment with penicillin. b, August 12, 1944, disappearance of the carbuncle and almost complete healing have occurred in 9 days.

was made, the principal method of arrest and control of the necrotizing process was emergency decompression of the involved area by surgical drainage followed by prolonged periods of immobilization. More recently chemotherapy with the sulfonamides used as a supplement to surgical intervention aided in the control of the infection but left much to be desired. Penicillin on the other hand has had a profound effect upon acute hematogenous osteomyelitis and has greatly modified both its management (8, 14, 19) and roentgenographic interpretation (9). In the group of 64 cases of acute hematogenous osteomyelitis treated with penicillin the mortality rate was remarkably low being 1.5 per cent. In general the other results of penicillin therapy varied primarily with the time of diagnosis and start of treatment falling into 4 groups.

The first group included those cases in which the correct diagnosis was made within the first 3 or 4 days, and adequate treatment was started immediately. The results were truly excellent surgical intervention usually being unnecessary and abscess formation infrequent. After a period of 36 to 72 hours, the fever, rapid pulse, bacteremia, and other general

signs of the severe infection began to disappear. At the end of a week the temperature was usually normal and the patient looked and felt quite well. The local signs of infection, such as tenderness, edema, and redness, also began to recede after a similar latent period. During the next 1 to 6 months a series of roentgenographic changes occurred in the involved bone which were minimal consisting of localized periosteal reaction or small areas of patchy decalcification of the underlying cortex, or both. These findings occasionally were hard to see and could be easily overlooked.

In the second group in which the diagnosis and treatment with penicillin were moderately delayed for 4 to 7 days, the general and local infections were brought under control by penicillin less promptly after a period of 2, 3, or more days during which little or no clinical response was evident. Localized soft tissue abscesses occasionally developed and when small, they were successfully treated by aspiration and local injections of a solution of penicillin. When large surgical drainage by incision was done to minimize further tissue destruction by the accumulated necrotizing bacterial toxins. If surgical drainage was insti-

Fig 5 V L., aged 33 years. a left, Carbuncle of face with diffuse cellulitis, thrombophlebitis of facial external, and anterior jugular veins, staphylococcal bacteremia, and bilateral pneumonia. Temperature, 106 degrees F at start of penicillin therapy b Effect of 10 days therapy with penicillin.

tuted the fall of temperature was usually prompt and not delayed for 36 or more hours as in the case treated without surgical intervention

After a week or more had elapsed periosteal reaction and localized patchy demineralization of the underlying metaphysis became evident in the roentgenograms and increased in extent and degree becoming most marked 1 to 5 months after the onset of the infection. Recalcification of the demineralized areas followed with re-establishment of a more normal appearance of the bone. Sequestration rarely occurred in this group.

The third group included cases in which the diagnosis and treatment were delayed for 7 to 10 or more days and those in which the infection was unusually severe. The local destruction of bone became very great and soft tissue abscess formation and sequestration occurred in most, but not all of the cases. The local infection was arrested with more difficulty in this type of case and longer periods of treatment with penicillin were usually required. Small abscesses were treated by aspiration and large ones by incision and drainage. Prolonged immobilization by cast in these cases seemed to be definitely indicated.

The bony changes as revealed by serial roentgenograms at the start of penicillin treatment showed extensive bone destruction which increased on subsequent examinations. Se-

questration occurred in most cases and in many instances the smaller sequestra were gradually absorbed spontaneously.

The fourth group included certain fulminating infections in which the patient would not live 48 or more hours to permit the maximum effect of penicillin. Surgical intervention after adequate preoperative preparation was necessary as an emergency measure in addition to intensive penicillin therapy.

In general the effects of penicillin included control of the generalized infection with sterilization of the blood stream, reduction of the mortality rate and decrease in the incidence of metastatic or secondary infectious complications. If metastatic complications such as staphylococcal pneumonia, pleuritis, pericarditis, thrombophlebitis, etc. already existed, penicillin was a powerful chemotherapeutic agent aiding in their control as an adjunct to surgical or conservative treatment as indicated. Thus the morbidity was also decreased.

There seems to be little doubt that adequate penicillin therapy can eliminate the necessity of emergency surgical intervention in most cases of early acute hematogenous osteomyelitis (8, 14, 19). It must be emphasized that early diagnosis can be made only on clinical grounds and that little or no help is to be expected from the roentgenograms for 10 or more days. If there is any doubt as to the presence of an acute osteomyelitis, it is better

Fig. 6 M. K. a, left, Severe acute hemolytic streptococcal cellulitis of face, neck, and scalp, with gangrene which was resistant to sulfonamide therapy. Temperature as 103 degrees F at start of penicillin therapy. b, Appearance of lesion after control of infection, separation of slough, and preparation of area for skin graft.

to start penicillin therapy rather than wait until the diagnosis is proved.

Of particular interest were the resultant roentgenographic changes which occurred in the involved bone treated with or without surgery. During the period of penicillin therapy evidence of bone damage was absent or confined to minimal changes such as slight periosteal reaction or small areas of demineralization in the underlying cortex. After the cessation of chemotherapy the periosteal reaction and mottled appearance of the underlying bone progressively increased, reaching a maximum 1 to 5 months after the onset of the infection. In this way the bone always looked worse a month or more after penicillin therapy than during it. This picture has been interpreted as being the result of spontaneous absorption of bone destroyed early in the infection and not as the result of continued destruction of bone by an extending chronic osteomyelitic process. Following this recalcification of the involved areas occurred often very rapidly. Meanwhile normal growth of the metaphyses, calcification of the adjacent

epiphyses, and return of function occurred. These facts suggested that adequate penicillin therapy may sterilize the infected bone converting an area of septic necrosis to one of aseptic necrosis. One of the most important aspects of this problem remains unanswered as yet: the question as to whether or not the infection has been completely cured.

Chronic osteomyelitis. In chronic osteomyelitis the results were usually disappointing unless penicillin therapy was used in conjunction with radical surgery. Spontaneous resolution of an acute exacerbation was noted in only 9 instances. In the remainder surgery was necessary along with penicillin to clean up the local infective process.

Acute secondary or postoperative parotitis. The control of acute secondary parotitis by chemotherapy is desirable since its arrest by conservative measures is uncertain and its control by surgical incision and drainage has certain disadvantages. Incision may result in unsightly scars, occasional injury to the facial nerve, salivary fistulas, or troublesome secondary infection (5). In addition a general ant-

In the treatment of anaerobic streptococcal infections, penicillin was far superior to the sulfonamides (3). *In vitro* studies showed its bacteriostatic action under anaerobic conditions for the anaerobic streptococci to be far greater than that of the sulfonamides. We have had an opportunity to use penicillin therapy on 22 cases of anaerobic streptococcal infections and the results are shown in Table IX.

Pneumococcal infections. The average pneumococcal infections seen in surgical practice respond very well to sulfonamide therapy in much the same manner as do the hemolytic streptococcal infections. Penicillin therapy was therefore reserved for those cases which were sulfonamide resistant and the results obtained in 70 cases are shown in Table X.

Tetanus. A clinical study (6) of 22 cases of established generalized tetanus seen in and about Cincinnati has failed to show evidence of any beneficial effect of penicillin on the course of this disease. There was no obvious

TABLE X.—SULFONAMIDE RESISTANT PNEUMOCOCCAL INFECTIONS—RESULTS OF PENICILLIN THERAPY

Clinical diagnosis	No. cases	Results			
		Excellent	Good	Questionable	Failure
Bacteremia	33	20	4		9
Erysipelas	8		8	2	6
Meningitis	9				5
Arthritis					
Pericarditis	1				
Abscess of neck	4		3		
Acute hematogenous osteomyelitis	1				
Peritonitis					

thetic and operation unquestionably throw an added burden upon the patient greatly weakened by some other primary disease which pre-disposed to the development of the acute parotitis. The simplicity of administration and the directness of action of effective chemotherapy largely obviate these disadvantages. Of 6 patients treated with penicillin 4 underwent complete and spontaneous resolution. A fifth responded satisfactorily to penicillin after failing to respond to Lugol's solution. The sixth underwent partial resolution with the formation of an abscess which was incised.

The general response of this infection to penicillin therapy followed the general pattern seen in other surgical infections treated by chemotherapy. An interval of 24 to 48 hours following the start of treatment preceded the development of obvious signs of clinical improvement. Thereafter the improvement was progressive and usually rapid.

Aerobic hemolytic streptococcal infections. While most of these infections respond promptly to sulfonamide therapy penicillin is also very effective and particularly valuable in those cases resistant to the sulfonamides (Fig. 6). The results of therapy in cases of hemolytic streptococcal infections treated at this Hospital most of which were sulfonamide resistant, are summarized in Table VIII.

Fig 7 G B a, left, Severe case of gas gangrene complicating compound fracture of tibia and fibula. Infectious process had produced complete gangrene of leg distal to wound and had spread through thigh to inguinal region.

Treatment consisted of midhigh gillotine resection penicillin parenterally since penicillin topically and therapy b, Appearance of amputation wound after treatment of amputation has been brought under complete control.

fall in the temperature or pulse rate as has been repeatedly seen in other infections susceptible to its action no decrease in mortality or morbidity nor any definitive decrease in the severity duration or frequency of the convulsive seizures which could be attributed to the action of penicillin. Exceptions were found in cases complicated by pneumonia or other secondary infections susceptible to penicillin in which the improvement that occurred was due to the effect of penicillin on the complicating infection and not on tetanus. The evidence indicates that the successful management of tetanus depends not on chemotherapy but on early diagnosis adequate serotherapy for neutralization of free toxin control of the convulsions and the administration of general supportive measures.

Human bite infections When once established this type of infection has been controlled with considerable difficulty in the past. Its necrotizing burrowing characteristics have resulted in prolonged morbidity extensive septic necrosis of the tissues including bone, toxemia, impaired function and even amputation. The results with penicillin therapy in 9 cases have been very promising and they indicate that penicillin is a valuable therapeutic agent for this condition being superior to the sulfonamides. In 5 of the cases the response to paren-

teral penicillin therapy rest, immobilization and elevation was excellent, the infection subsiding quickly and spontaneously with little or no evidence of residual infection or damage. The response was good in 4 other cases when penicillin was used in conjunction with incision and drainage, and questionable in the remaining infection.

Ratbite fever Ratbite fever is essentially an invasive wound infection of two clinical types: (1) sodoku caused by the *Spirillum minus* and (2) the septicemia form produced by *Streptobacillus moniliformis* (10). The endemic Japanese form, sodoku, has responded to arsenotherapy but no satisfactory form of treatment was known for the streptobacillary type. The first 4 cases of ratbite fever caused by the *Streptobacillus moniliformis* which were treated with penicillin were studied at the Cincinnati General Hospital. The results of penicillin therapy in these 4 cases were excellent: 3 with sterilization of the blood stream, each fall in temperature and pulse, disappearance of rash and arthritis, and shortening of the course of the disease. In addition studies *in vitro* indicated that penicillin has a powerful bacteriostatic effect on the *Streptobacillus moniliformis*.

Gas gangrene. Penicillin is by far the chemotherapeutic agent of choice in the control of

established gas gangrene. Clinical investigations indicate that parenteral penicillin used in conjunction with surgery gives encouraging results, but only when it is given in relatively large doses of 200 000 to 400 000 units and 800 000 units per day (11 16 18). In a study of experimental gas gangrene (7) the therapeutic value of penicillin has been determined quantitatively.

Average doses of penicillin had no measurable effect but large doses corresponding to approximately 1 000 000 units given every 3 hours had a very definite effect reducing the mortality prolonging the life of the guinea pigs and localizing the lesions. Without surgery however discontinuation of penicillin was followed by prompt spread of the lesion and ultimate death. These experiments indicate clearly that penicillin in large doses is a valuable adjunct to adequate surgery in the treatment of established gas gangrene since it limits the spread of the lesion prolongs the period during which surgical decompression and excision of involved muscles can be done successfully and reduces mortality. This corresponds to the clinical impression of Jeffrey and Thomson obtained in 33 cases of gas gangrene that penicillin can arrest the progressive myositis but that radical surgery is still the main factor in treating the disease. In our clinical experience of 12 cases of gas gangrene the use of penicillin in conjunction with surgical decompression or amputation seemed to be of definite value in overcoming the invasive manifestations of the infection. If the diagnosis was made at an early stage while the gangrene was more or less localized and incipient, radical decompression of the involved fascial compartments by free longitudinal incisions and excision of the infected muscle usually resulted in the arrest of the process and the saving of the extremity. If the diagnosis was made late when the process was extensive and had caused irreversible gangrenous changes in the extremity implying loss of function of the limb open amputation of the guillotine type or some modification became necessary (Fig 7). At the present time it is inconceivable that any type of serotherapy or chemotherapy can replace good surgery in the treatment of gas gangrene.

Actinomycosis. Penicillin has been much more effective than the sulfonamides in the treatment of actinomycosis but in our experience it is used most effectively in conjunction with sulfadiazine or sulfamerazine. Penicillin given in full doses over a prolonged period of at least 4 to 8 weeks in association with sulfadiazine which is continued under control for an additional 4 to 6 months has given us the best results. Very satisfactory results were obtained in the cervicofacial type and other cases of both abdominal and thoracic actinomycosis have undergone arrest and rather spectacular regression under this management with progressive decrease in size and finally disappearance of the tumor masses and pain. Whether or not complete cures have been obtained in these cases remains to be seen.

SUMMARY

It is evident that the sulfonamides and penicillin are very effective and useful agents in the treatment of many infections commonly encountered in the practice of surgery. Penicillin is far superior to the sulfonamides in the treatment of infections caused by the staphylococcus and it has been particularly useful in the cases of infection caused by sulfonamide resistant gonococci hemolytic streptococci and pneumococci. It is also the chemotherapeutic agent of choice in gas gangrene ratbite fever actinomycosis anaerobic streptococcal infections and human bite infections. The use of increasingly large doses of penicillin permitted by its very low toxicity is gradually extending the field of effective chemotherapy in other infections produced by less susceptible bacteria. Penicillin has been strikingly effective in diffuse or generalized staphylococcal infections which have been diagnosed and treated early with penicillin with the exception of those caused by a resistant strain or those complicated by acute vegetative endocarditis. The early treatment of diffuse infections caused by the staphylococcus or streptococcus often was followed by such prompt and complete arrest of the destructive bacterial process that suppuration did not develop and surgical intervention either became unnecessary or limited to more localized measures. In

the management of suppurating surgical infections caused by susceptible bacteria, penicillin therapy has had a striking beneficial effect on mortality and morbidity but the fundamental surgical principles of early accurate diagnosis early treatment rest, adequate external drainage correction of altered physiology and vigilant supportive treatment remain as important as ever

CANCELLOUS BONE GRAFTS TO THE JAW

T G BLOCKER, Jr MD F.A.C.S Galveston Texas

THE problem of bone grafting in the lower jaw merits serious consideration even though it is met with infrequently in civilian practice. Distortion of appearance which results from mandibular loss in the course of surgery of malignancy and following severe infection or trauma is secondary in importance to disturbance of

speech and to the impairment of mastication and deglutition which affects profoundly the individual's entire nutritional status. In war surgery the necessity of bone grafting to the lower face arises rather commonly because of the high incidence of massive maxillofacial injuries from bullets and shell fragments.

Mandibular bone grafts were first employed 30 years ago during World War I by the German, French and English American groups of workers with perhaps a thousand cases re-

Presented in the symposium on Plastic Surgery of the Head and Neck, before the Clinical Congress of the American College of Surgeons, Cleveland Ohio, December 16-20, 1946.

Fig. 1. O. R. I., Pfc., age 31 years, received a shell fragment wound June 29, 1944, with loss of considerable soft tissue of the chin and bony loss of the symphysis and anterior half of the right body of the mandible. It was necessary to readjust soft tissues for better coverage before insertion of a bone graft, and a labioalveolar sulcus was created later by a stent graft in order that a functioning

denture could be used. a, Appearance on admission. b, Roentgenogram showing bone loss. c, Interlocking cap metal splint for immobilization. d, Roentgenogram showing cancellous bone graft bridging the defect. e, Appearance following bone graft.

ported in all. A variety of sources were employed in the remedy of small losses of bone and in ununited fractures. These include

1. Sliding or pedicle grafts from the mandible for losses not greater than 3 centimeters in the symphysis or body.
2. Cortical grafts from the tibia.
3. Osteoperiosteal grafts—thin shavings of bone and periosteum about 2 millimeters in thickness—for small bony defects not associated with disturbance of contour.

4. Rib grafts

5. Clavicle grafts employed in pedicles for the neck for restoration of the symphysis and overlying soft structures of the chin.

6. Grafts from the ilium, particularly for large losses of bone and distortion of normal contour.

During recent years the use of iliac grafts has been the method of choice, although some workers, notably Barrett Brown, employ the rib whenever practicable.

(Legend on opposite page)

The literature on theories as to the mechanism of bone regeneration is voluminous and has influenced considerably the operative technique. For a long time it was felt that periosteum was indispensable but experimental and clinical evidence has demonstrated that neither periosteum nor cortical bone is necessary for successful grafting. The superior qualities of cancellous or spongy bone provide for rapid vascularization and earlier stabilization and union for this reason small chips of part-cortical part-cancellous bone are becoming increasingly popular in orthopedic and maxillofacial surgery when it is felt that immobilization can be maintained without the use of cortical bone as a splint for fragments. The employment of large blocks of pure cancellous bone from the ilium is the most recent innovation in bone grafting. And while other workers may be able to demonstrate equally good results with other methods of reconstruction of mandibular defects we have found cancellous block grafts an extremely satisfactory medium of repair. The ilium is readily accessible and furnishes a large amount of available spongy bone. Following removal

of all cortex the graft is easily cut and shaped to fit the requirements of the individual case. The use of chips alone is rather haphazard and it is difficult to maintain good contour. For extensive defects such as angle-to-angle loss of bone we have employed at times a tantalum tray to give proper shape to the jaw. In these cases more than one block graft is used, and cancellous chips are packed around the open spaces.

With present-day dental appliances there need be no dependence on the mandibular graft for any part of fixation. Cancellous bone very quickly develops strength and evidence of firm bony union within 8 to 14 weeks time after operation when dentures may usually be fitted. We have been able to observe grafts directly 5 to 6 months after surgery when exposure is made to add a cartilage implant for improvement of chin contour. They show smooth white bone with a well-developed pseudoperiosteum and on stripping of this membrane numerous nutrient vessels are seen entering the bone.

The most important requirements for success in bone transplantation are adequate sup-

Fig. 3. V. A. Mc., age 20 years, received a machine gun bullet wound of the face October 17, 1944, with violation of the soft tissues about the lower lip and floor of the mouth and loss of the symphysis and anterior half of each body of the mandible. a, Appearance on admission. b, Appearance following rearrangement of local tissues to stop the salivary leak and raising of pedicle soft tissue from the chest to be used for reconstruction of the floor of the mouth prior to bone grafting. c, Interlocking cast metal splints for stabilization of the fragments. d, Appearance following bone graft.

ple cover free of scar tissue and induration, absence of infection and avoidance of contamination at the time of operation and proper preoperative and postoperative immobilization of fragments. The necessity of having resilient soft tissue covering has not been adequately stressed and here time is an inescapable factor in the elimination of wound reaction. For avulsion deformities pedicle flaps from the thorax and abdomen must be employed. Less severe defects may be taken care of by rotational flaps and other methods of rearrangement of local tissues. Even small adherent scars should be removed several weeks before bone grafting with complete excision and wide undermining to give relaxation in closure. Operation should never be performed through a wide cicatrix or through an indurated area. Removal of loose sequestra and fragments of teeth hastens the subsidence of localized drainage and infection. We are not yet convinced that early operation is advisable

even with the use of penicillin and it has been our custom to delay bone grafting for a minimum period of 2 months following last drainage from the area. The great majority of our cases have waited over 6 months after subsidence of active evidence of infection.

Bone grafting to the jaw requires close cooperation of both surgeon and dentist. The dental surgeon assumes charge of all mechanical devices for immobilization of fragments before and at the time of operation and looks after the patient's oral and dental hygiene. Proper emphasis must be placed upon improvement of the general physical condition as well with correction of anemia, weight loss, and protein imbalance.

The chief problem in individual bone graft procedures of the mandible is the method of fixation and immobilization to be employed. Various factors must be taken into consideration—size and character of the defect, position of teeth in the upper and lower jaw and state

Fig. 4. R. M. B. Corporal aged 25 years, received a shell fragment wound June 10, 1944, with avulsion of soft tissues of the chin and floor of the mouth and loss of the right body and symphysis of the mandible. a, Appearance on admission showing granulations and draining sinuses.

b, Exposure of mandibular defect at operation 1 year after admission. Soft tissue loss has been replaced with a pedicle flap from the chest. c, Tantalum tray containing cancellous block graft. d Appearance following operation. e, Profile view.

of occlusion of the fragments. Because of the danger of opening into the oral cavity at the time of operation the position of fragments cannot be altered at that time except in angle defects or where the fragments are edentulous.

If both fragments are edentulous some modification of the Gunning splint is used during the waiting period and also following bone grafting. At operation we usually employ some type of internal fixation such as a piece of perforated tantalum shaped over an impression of a normal cadaver mandible.

Where one fragment is edentulous and the other contains teeth the latter is kept in occlusion by a flange splint. The edentulous portion at operation is liberated on all surfaces, placed as nearly as possible into normal

position and maintained there by a wire through the angle tip or ramus which protrudes through the skin and attaches to a bar coming around the face from the intraoral splint.

Where both fragments contain teeth a cap metal splint with rigid crossbar is very satisfactory preoperatively. At the time of insertion of the graft two interlocking cap metal splints are used to hold the jaws absolutely immobilized. At the time of operation we have employed either endotracheal anesthesia or a combination of (1) high bilateral intraoral mandibular block with 2 per cent novocain (2) local novocain infiltration and (3) spinal anesthesia for removal of bone from the ilium. We prefer the second method because of the advantage of novocain adrenalin solution in

Fig. 5. J. L., Pvt., aged years, received a shell fragment, 6000 of the face October 9, 1944, with avulsion of soft tissues of the chin and loss of the symphysis and anterior two-thirds of each body of the mandible. a, Appearance on admission. b, Pedicle flap raised from chest to allow for shifting of neck flap upward into defect. c, Roentgenogram showing block grafts in tantalum tray. d, Appearance following operation showing contour of the mandible. Note pedicle tissue has been smoothed out on neck. e, Final appearance following rearrangement of soft tissues of chin.

minimizing bleeding in the operative field. In addition the patient is less likely to develop postoperative respiratory distress and nausea when a general anesthesia can be avoided.

TECHNIQUE

The operative technique is as follows:

Incision is made parallel to the lower border of the mandible with care taken to prevent injury to the mandibular branch of the facial nerve. This nerve can be avoided by dissection downward external to the platysma for about 2 centimeters below the inferior border before approach is made to the bone fragments. About 2 centimeters of bone is exposed on each side where fragments contain teeth. For ramus, angle, or posterior edentulous fragments exposure can be made by stripping the periosteum for long distances without danger of entering the oral cavity. Edentulous fragments are detached thoroughly and replaced in normal position.

Eburnated ends of fragments are cut off by sharp rongeurs, and the outer cortex of the

mandible in the recipient areas is removed with a dental burr until an area of bleeding bone sufficient for good contact is obtained.

Meanwhile the iliac crest has been exposed subperiosteally by another operative team. A large section of ilium is cut out with a sharp osteotome and placed on a wooden block for removal of all cortical bone, which is then discarded. The donor area is closed in layers with a deep removable No. 32 wire suture and No. 36 interrupted sutures are used for the skin. Pressure dressing is applied.

The graft is shaped with sharp-cutting rongeurs, and all cancellous chips are saved to be packed later into open spaces in the graft bed. The transplant is placed in position as both an inlay and onlay graft and is immobilized by a single strand of No. 32 stainless steel wire at each end. At least 2 centimeters should be in contact with the bleeding bone on each fragment. Although there may be marked protuberance externally at first, rapid absorption takes place and the contour of the mandible is quickly established after function begins.

Fig. 6. F W P Pvt., aged 20 years, received a shell fragment wound July 7, 1944, with avulsion of the lower lip, chin, and floor of the mouth, and loss of the symphysis and anterior one-third of each body of the mandible. a, Appearance 3 months after injury. b, Pedicle flap in position. c, Roentgenogram showing bone loss. d, Interlocking cap metal splint used for immobilization of fragments before bone grafting. e, Roentgenogram showing bone graft in position. f, Appearance following firm bony union. g, Appearance following excision of outer covering of flap and replacement with skin from the face. Further "touching-up" procedures are yet to be carried out.

Complete hemostasis is obtained by ligation of all bleeding points with No. 40 wire. Closure is made in layers, and firm pressure dressing is applied. It cannot be too strongly em-

phasized that there must be no tension on the wound edges and it may be necessary for proper relaxation of the tissues to undermine the skin for considerable distance.

Fig. 7 J. P. P. P., aged 9 years, received shell fragment wound of the face June 24, 1914, with fracture of the left mandible and maxilla. Following removal of an unsuccessful cartilage graft because of drainage, a large cancellous bone graft was placed over the receding portion of the maxilla, with good contour resulting. a, Appearance on admission. b, Final contour.

(Reproduced through courtesy of the J. B. Lippincott Company from article by Blocker.)

Fig. 8 C. C. Mc., aged 9 years, received shell fragment wound of the face July 5, 1914, with evulsion of soft tissue and loss of the major portion of the left maxilla. The soft tissue loss was replaced by pedicle skin prior to restoration of contour by cancellous block graft. Appearance on admission. b, Appearance following operation. It is planned to remove the outer covering of the pedicle flap as completely as possible at a later date and replace it with a rotational flap from the neck.

(Reproduced through courtesy of the J. B. Lippincott Company from article by Blocker.)

In over half of our cases closure was made with fine silk, but as we felt that in two instances drainage occurred as a result of buried silk sutures, we began to use a single removable stainless No. 36 wire for the deeper layers and continuous running stitch of No. 38 wire for the skin.

AFTER-CARE

Postoperatively patients are kept in a semi-erect position and watched closely for evidence of respiratory difficulty. In one instance we found it necessary to open an intraoral splint for 24 hours to relieve obstruction. Liquids are given by syringe or tube and gradually the patients learn to put semisolid foods around the splints with the fingers. Protein and vitamin intake is given careful attention.

Routinely we have given for 5 days postoperatively 20,000 units of penicillin in $\frac{1}{4}$ per cent novocain solution every 3 hours. Pressure dressings to both donor area and face are maintained for 10 days, and frequent mouth wash is used for oral hygiene. Patients are usually ambulatory by the end of 2 weeks. After 7 or 8 weeks the cap metal splints are released, and the state of clinical union is inspected. If the fragments are not absolutely rigid, splints are left in place for another 2 to 4 weeks before removal. Dentures are fitted within 8 to 14 weeks if normal buccal and labioalveolar sulci are present. Otherwise these must be reconstructed by stent grafts 4 to 6 months later.

During the past $2\frac{1}{2}$ years we have seen in an army plastic surgery center 68 patients who have required bonegrafting because of mandibular loss greater than 2 centimeters. Eight of these showed massive avulsion wounds which required replacement of soft structures by pedicle flaps prior to bone grafting. Two of the 68 patients are still waiting final operation pending subsidence of tissue reaction.

In the remaining 66 cases blocks of pure cancellous bone from the ilium have been employed for defects varying from 3 to 15 centimeters in length. Drainage has occurred in 10 instances twice from buried silk three

times from inadequate coverage and in 5 cases from accidental opening into the oral cavity. Half of these cases have had successful union in spite of drainage. Four have had partial loss of graft. 2 of these have since been regrafted without complication. In the fifth case it was necessary to remove the transplant because of infection. Failure has been attributed in 3 instances to insufficient cover plus difficulty in fixation for one reason or another in 2 there had been infection following entrance into the mouth.

No disability has been noted in any patient from the removal of bone from the ilium. Drainage has occurred in 2 instances once from buried silk and once from a small piece of rubber tissue inadvertently left in the wound.

In addition to 68 bone grafting procedures to the mandible in 66 patients cancellous iliac grafts have been employed for restoration of contour in 18 deformities of the maxilla 5 of the nose and 2 of the supraorbital margin. Drainage occurred in one instance but successful final union was obtained in every one of these cases.

SUMMARY

In summary we believe that iliac block grafts of pure cancellous bone form the most satisfactory material for relief of large and small bony defects in the mandible. The large percentage of cases without failure cannot be attributed to the choice of graft alone however. We must not overlook the value of chemotherapy in the treatment and prevention of infection nor disregard the importance of suitable mechanical fixation of fragments. Above all we must not forget that the background of all transplantation procedures is the proper preparation of the tissues themselves. In no other branch of surgery is the old adage so true, that haste makes waste.

MODERN METHODS IN THE TREATMENT OF FRACTURES

EDWIN W RYERSON M.D. F.A.C.S., Chicago, Illinois

IN the early days of the human race, nearly all fractures were caused by falling from a sufficient height and were usually simple fractures of the long bones. As the centuries rolled by and warfare became developed to a higher grade than wooden clubs and stone axes, compound fractures became more common and were less easily repaired. With the advent of gunpowder and the hazards of more rapid transportation fractures occurred with much greater frequency and began to attract the serious consideration of the physicians and surgeons of those times.

Seventy years ago a compound fracture of an arm or leg almost invariably required immediate amputation to save the patient's life, but the development of antiseptic and aseptic methods of treatment began to offer more hope of saving these damaged limbs. Forty years ago the rapidly increasing numbers of automobiles introduced the tremendous risks of high speed travel on the highways and the byways of the world. Thirty years ago the first World War produced the enormous dangers of high explosives and fast airplanes and these dangers were multiplied many times over in the war which ended only last year. Or has it really ended?

What has been learned in the last few decades about the treatment of fractures? Since 1900 forty six years ago I have been interested in orthopedic surgery and in fractures. I have seen the rise and sometimes the fall of many different methods and ideas in the treatment of broken bones.

The one dominant purpose of treatment is to produce a satisfactory union of the fracture, with re-establishment of the normal function in the shortest possible time.

In the Fracture Oration of 1935 Paul Magnuson presented briefly and graphically

Dr. Ryerson is Consulting Orthopedic Surgeon, St. Luke's Hospital, Chicago.
Fracture Oration, presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 26-30, 1946.

the salient points of fracture treatment from the days of the Egyptians 4500 years ago, the Hippocratic era 2400 years ago, and the works of Galen up to the year 900 Anno Domini. Then came the long centuries of the Dark Ages when no progress was recorded until the Renaissance. In the 14th century interest in fractures was revived and from that time the value of many of the almost forgotten old principles began to be recognized. Methods of traction and countertraction, the basic foundation of the treatment of fractures of the long bones, became simplified and improved. Buck's extension Thomas's splint (which was originally designed for knee disorders) and Hodgen's suspension splint gradually assumed their well deserved importance, together with the improved types of adhesive plaster. Then in 1895 came Roentgen's discovery of the x ray which visualized both the good and the bad results of treatment, and made possible some much needed improvements in the handling of fractures.

Now it became easy to determine accurately whether or not the alignment of a fractured femur was satisfactory or whether the traction was pulling the bones too far apart.

Next came the development of skeletal traction by Steinmann's pin and Kirschner's wire, in cases in which adhesive plaster could not be used. These devices were not free from the danger of infection and had to be carefully watched.

In 1910 Arbuthnot Lane popularized his method of applying a steel plate, by open operation screwing it across the fracture line by four or six or eight screws. This simple and easy way of reducing and securing fractures of the long bones swept the country like a tornado. It seemed so rational and so satisfactory that hundreds of surgeons purchased the plates and the few special instruments, and without following the meticulous technique perfected by the originator proceeded to plate many simple fractures of the long bones. I do not know how many times I have been asked

to see a boy or a girl with a fractured femur who was about to have a Lane plate applied by an enthusiastic surgeon. In most of these cases when it was explained that the overriding and the malposition could be corrected by a few days of traction and suspension in a comfortable Thomas splint, and that in 6 or 8 weeks union would be strong enough for a caliper splint or a plaster-of Paris spica the doctor and the patient were willing to avoid the operation.

There are two basic reasons entirely apart from the danger of infection why a plate of the Lane type or the Sherman type or any similar type is not the ideal method of treatment. First, it does not immobilize the fracture completely, because a certain small amount of motion will always be present in rotation and in lateral bending toward the plate.

Both of these motions could be avoided by applying a similar plate to the opposite side of the bone but few surgeons have had the hardihood to attack the bone on both sides. In oblique fractures a transfixion screw applied at right angles to the line of fracture will prevent most of the mobility but does not work so well in transverse fractures. Secondly when a Lane plate is applied the ends of the fragments undergo a small amount of absorption so that a definite space is left between the ends. It is true that in many cases enough new bone is formed to obliterate this empty space, and the fracture unites but it does not unite as rapidly as it would if the bone ends were in firm contact. Moreover the external callus formation develops upon the opposite side of the fracture and does not cover the plate, except in children so that the ultimate ossification of the fibrous tissue between the ends of the bones is greatly delayed. This external callus may become very large when the immobilization of the fracture is inadequate. Even a long plaster-of Paris cast, from the chest to the toes does not furnish complete immobilization in most cases of fracture of the shaft of the femur.

I do not deny that in many hospitals and clinics the plating of simple fractures of the long bones has shown excellent results but such operations should be performed only when a satisfactory result cannot be obtained

by conservative mechanical means and when the surgical standards of the operator and of the hospital are of the very highest grade.

Because of the many disappointments following the widespread use of the early types of the Lane plates whether from mechanical defects technical errors or infections, other investigators have been busily devising different methods. The old and reliable principles of manual reposition traction and counter traction and fixation by plaster of Paris and splints have become less understood and less popular. This I think is largely due to the fact that the conservative mechanical treatment of long bone fractures requires the careful time consuming attention of the surgeon himself. He cannot safely delegate this attention to anyone else. A leg or an arm in a traction apparatus must be seen every day by the man who is responsible for the ultimate result. Residents and internes do not always notice that the adhesive plaster is cutting into the skin or is losing its pull at important points. Because this constant attention is necessary and because a day has only so many hours, it is perfectly natural that busy surgeons should welcome any methods which would reduce the time element required for proper results. If such methods are safe, sane and satisfactory we should use them but we must always remember that the union of a fracture takes so many weeks or so many months and that we cannot make broken bones grow together any faster in 1946 than the Egyptians could four thousand years ago.

What are some of these newer methods and to what extent can they be recommended for general use?

Many years ago various types of nails and screws were employed in attempts to fasten together the broken bones. Considerable success resulted in many cases but the ever present danger of infection made such treatment always a definite hazard. The advent of the sulfa drugs penicillin and other fungus derivatives has removed some of these dangers but there is still no substitute for aseptic surgical technique. Stainless steel and vitallium have replaced iron and plain steel and we can no longer use metals which undergo erosion or cause electrolytic reactions in the

body tissues. Metallic fixation of fractures has assumed a very important place in bone surgery especially in certain kinds of fractures. The neck of the femur the olecranon process of the ulna, the patella, and the shaft of the tibia may present problems which may legitimately be considered suitable for open operation. Years ago Kellogg Speed in one of these Fracture Orations applied the name 'The Unsolved Fracture' to the very dangerous fracture of the neck of the femur. The medical literature has been full of articles about different methods and devices for the treatment of this lesion. When I was a young man some of the surgeons were using carpenter's screws or nails, with occasional success but with frequent failure. Smith Petersen's three-flanged nail was an enormous improvement over the earlier types, but even today there are clinics where lag-screws, threaded wires, and other devices are preferred to the flanged nail.

Some of the recent publications do not emphasize sufficiently the enormous necessity of accurate reduction of the fracture before it is nailed or screwed. In many of the articles, roentgenograms are shown which reveal imperfect replacement of the fracture before the nail was inserted. This did not always produce a failure of union but it is certainly not desirable and it is usually the result of inadequate x-ray control. Anteroposterior x-ray films cannot be relied upon to show accurate reduction of the fractured ends and it is extremely difficult to make satisfactory lateral films with the patient's legs fixed firmly in the traction apparatus. No surgeon should attempt to nail a fracture of the neck of the femur unless he can obtain good lateral films on the operating table at all stages of the operation, without disturbing the hip-joint or the operative technique. This means that such patients should be cared for in a hospital with all of the requisite equipment and personnel. It is major surgery of the most difficult type.

The purpose of this lengthy discussion is to emphasize the tremendous importance of developing in every community a team of surgeons who will be able to treat properly the cases of fracture of the neck of the femur and who will have the requisite instruments and

x-ray facilities and technicians, without which no one can accurately reduce and nail such fractures. One day in August I examined the x-ray films of 3 cases of this kind which had been nailed in other cities. Not one of these fractures had been properly reduced before the nailing and all 3 had failed to unite. It is highly probable that these unfortunate results were due to imperfect lateral x-ray films made on the operating table, and I have seen many similar examples, some of them occurring in my own practice. Unless the x-ray control is clear and accurate it will be necessary to open the hip-joint in order to be sure that the reduction is satisfactory and that the nail is put in the proper place. This type of open operation adds greatly to the danger of shock and of infection and is practically never necessary when good x-ray films are available during the operative procedures.

To make my position perfectly clear the following plan seems to be the best for the treatment of fractures of the neck of the femur.

The patient is placed upon an orthopedic traction table of the Albee, Hawley McKenna, or similar type. The displacement is carefully reduced by the Leadbetter maneuver or by traction. X-ray films are made in anteroposterior and lateral planes, one of the two portable tubes being located between the thighs, the other directly over the hip-joint and two or three feet above the field of operation. The perineal post on the sacral support should be of wood or aluminum, so that no manipulation will be necessary for the lateral views. When the reduction is shown to be satisfactory both legs are securely fastened to the traction apparatus. A 5 inch incision is now made to expose the outer surface of the femur and a long wire marked in half inches, is drilled upward and inward from a point well below the trochanter. It is wise to make a hole through the outer cortex with a quarter-inch drill before starting the wire, so that the direction of the wire can more easily be changed without binding or bending in the thick cortex. When the wire has been inserted to a depth of 3 or 3½ inches, new x-ray films are made to check its position. If not satisfactory the wire is withdrawn and reinserted until it is

in proper position. This may require one or two trials, with corresponding x ray films. A little time may be saved by using another wire, leaving the first in place as a guide. When the position is found to be correct, a cannulated stainless steel or vitalium Smith Petersen nail is threaded upon the wire and is driven along it into the neck and head of the femur. The length of the nail is estimated by the calibrations of the wire. Again x ray films are made in both directions, and if satisfactory the wire is pulled out and the wound closed.

You will see from this description the enormous importance of the x ray examinations, and the complete futility of attempting this kind of operation unless such rapid and accurate roentgenographic control can be furnished. Good anteroposterior views can be made with great ease but the lateral views require special equipment and technique.

I have not mentioned the use of screws, lag screws, or the various threaded or unthreaded wires, because I believe that the Smith Petersen Johansson nail is better than any of them for general use.

A few words about the after treatment. Over the usual dressings a firm, elastic spica bandage should be applied from the waist to the knee, and a foot-piece or sling should be used to prevent outward rotation of the thigh.

It is important to prevent outward rotation of the thigh as the patient lies in bed because the weight of the thigh and leg exert a downward and outward pull upon the nail tending to separate the fragments. It is not wise to allow early sitting and standing without some form of partial immobilization of the affected hip although some writers encourage it.

We must remember that at least 4 months are required for bony union in these cases and that union is made by the internal deposit of new bone, and not by external callus formation.

Aseptic or avascular necrosis of the femoral head is a complication of intracapsular fractures seen less frequently than after dislocations of the hip but nevertheless sufficiently often to influence the ultimate prognosis. The artery in the ligamentum teres supplies only a small portion of the head, and, indeed, is some-

times absent. The main blood supply comes from the arteries of the capsule and if these arteries are occluded or are too small the head becomes necrotic. At present, there is no certain means of improving the blood supply although drilling and bone-grafts offer some hope. Perhaps the best form of treatment is to prevent any weight bearing on the femoral head by the use of crutches and a caliper splint, or by long-continued traction trusting that Nature will provide a new blood supply by the slow growth of small arterioles and by creeping substitution. This requires a long time and in some cases fails to occur in which event the patient has a painful and disabled hip-joint which may need a reconstruction operation or an arthrodesis to produce an ankylosis of the joint.

Let us now consider the other types of fractures which may usually be considered suitable for operative treatment. The patella and the olecranon process of the ulna if the fragments are widely separated will unite more satisfactorily and more rapidly if they are mechanically fastened together by one of the accepted operative methods. Spiral or oblique fractures of the shaft of the tibia may be extremely difficult to retain in good position by conservative treatment and it may be wise in such cases, to fix the fragments together by transfixion screws, or even by stainless steel plates. The fibula unites much more rapidly than does the tibia and sometimes holds the fractured surfaces of the tibia so far apart that they cannot unite. Cases of this kind require operation.

For many years the surgical literature has been flooded with articles advocating the use of mechanical devices for the reduction and the fixation of fractures of the long bones. The catalogues of the instrument makers and the published articles of the designers show in fascinating detail the very ingenious devices and the remarkably successful results. The basic principle of all of these contrivances is identical. This principle is to drill two strong pins into the shaft of the bone above the fracture and two more similar pins below the fracture as far away from the fracture itself as possible and to connect each pair of pins with a clamp to hold them rigidly to-

gether. These two units are then used to manipulate the fractured ends into accurate apposition. In difficult cases an ingenious traction frame has been devised to aid in this manipulation. When good position has been attained, the pin units are connected by rods clamped firmly to them, or by short plaster-of-Paris casts molded around the pins. It is not to be denied that this method is very valuable in certain types of fractures. It furnishes good apposition and good control of nearly all types of fractures, and allows early and free movement of the joints at either end of the broken bone. It is, however, neither so simple nor so safe as the inventors and manufacturers would have us believe. It requires considerable skill and experience to drill the pins into the proper positions, whether the pins go entirely through the limb or stop after penetrating both cortices of the bone and project only from one side of the limb. It is also not easy to prevent infection from occurring along the track of the pins, as there is always some seeping discharge from the pin holes, but the advocates of the method state that osteomyelitis is very rare.

The best known of these devices are the Stader, the Haynes, the Griswold and the Roger Anderson types, and of these the Anderson instruments seem to be the most generally satisfactory. They are all modifications and improvements of the old Lambotte ideas, and in a very small proportion of fractures they may be very useful.

Another revival of ancient methods was described by Kuntscher in 1940, who drove a long steel rod into one end of a fractured long bone down through the medullary canal across

the line of fracture. These rods were used chiefly in Germany during the second World War and have achieved some popularity in the United States. One of the advantages of this method is that the broken ends of the bone are pulled into close apposition by the action of the muscles, so that union is much more rapid than when Lane plates are used. The fact that the medullary canal is plugged up by the rod seems to have no deterrent effect upon the union of the fracture.

About thirty years ago Hey Groves treated a fracture of the upper third of the femur in this way, using an iron rod, but he complained that the rod was not strong enough to resist the muscle-pull, and so the femur became bent at an angle. If he had put the leg up in a Thomas splint or in plain traction apparatus, after the operation, the result might have been better. With the new stainless steels, the method may be useful in selected cases.

It must be admitted, in discussing the various kinds of operative treatment of simple fractures, that the advent of the sulfa drugs and the fungus derivatives has made open surgery much safer than it was a few years ago, but we must not lose sight of the fact that the majority of fractures can be treated successfully by the older conservative methods. We are going through a transitional period at the present time, both surgically and politically, and I do not want our young physicians impressed with the idea that fracture treatment necessarily means a machine-shop full of tools to repair every kind of broken bone.

The best fracture surgeon uses the fewest gadgets.

THE SURGEON AND HIS TRUST

With Special Reference to Safe Conduct of the Patient through Operation

OWEN H WANGENSTEEN M.D. F.A.C.S. Minneapolis, Minnesota

THE safe conduct of a patient through operation demands the following (1) adequate preparation of the surgeon (2) careful and precise preparation of the patient (3) satisfactory preparation of the patient after operation. All of these items are important. Inasmuch as many of the important items relating to care of the patient before and after operation the subject of this symposium discussion have been dealt with in an eminently satisfactory manner by the other participants I have elected to devote my remarks principally to a somewhat philosophic consideration of the surgeon's own preparation for his responsible tasks. I do not interpret my opportunity of speaking last as affording me the privilege of acting as moderator in this discussion. In the final analysis, you and time are the ultimate arbiters and umpires of what is said here.

THE FUNCTIONS OF SURGERY

The very nature of surgery stamps it as a sacred trust. By general agreement, surgery is invoked only when the desired objective cannot be achieved satisfactorily by non-surgical means. It is the purpose of surgery to preserve life and to restore normal function in so far as is possible and at the least risk to life and without compromise of the patient's future welfare.

FORMALITIES OF SURGERY

Any enterprise which achieves its ends through employment of such extreme means as surgery must of necessity observe certain formalities. In saying this I am not alluding to fatuous conventions and empty ceremonies but to compliance with rules of conduct which

From the Department of Surgery University of Minnesota Medical School, Minneapolis.
Presented in the symposium on Care of the Patient before and after Operation, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-30 1946.

time and practice have shown to be valuable guides.

The items listed above which have to do with the safe conduct of a patient through operation are mutually interdependent. One component is unlikely to afford promise of success without the co-operation of the others. A well trained surgeon who comes well prepared for the operation and who performs a superb dissection but who neglects the preparation of his patient before operation or his care after operation is not doing the best for his patient, and the surgeon who hungles the dissection stands in the way of recovery of his patient. Yes poor preparation of the dissection is alas the agency through which some patients who undergo surgery with the hope of having their lives made happier and longer have them shortened. How poor management of the problem of hemostasis in any type of surgery but particularly in operations involving large blood vessels or performance of anastomosis in the gastrointestinal canal which is architecturally unsound may shorten the lives of patients needs no elaboration. What surgeon would not prize highly an opportunity to be given a second chance to rectify an error of commission which shortened a patient's life? But an operation like any biological experiment is performed only once. Why not prepare well for it? Death is so final!

Yet, we see surgeons hurrying through operations as though their time were more important than the safety of the patient. Has not the fallacy of the 'get in quick and out quicker' approach to surgical problems been exposed sufficiently? No amount of best care before and after operation can undo the harm of an operation badly performed.

Wise surgical planning limits the surgeon's range of activity. The Army Medical Corps in World War II had a record of accomplishment in the management of difficult surgical problems which was unique in the annals of medi-

cine. The success of that undertaking was the result of planning organization and the selection of individuals with satisfactory training to do a given job. In our own work, we are left largely to our own devices in these matters. The product of our endeavors is dependent in large measure upon how well we have planned and the care with which organizational detail has been carried out. The range of operations which any one surgeon may perform is also a matter of personal choice. This latter item is a matter which demands some standardization among surgeons, just as much as particulars of planning and organization. There are still a few surgeons who affect to believe that they can take all of surgery for their province. They know as well as anyone that their performance in such a wide category of operative procedure is substandard in some of these areas, when judged in the critical light of what constitutes good practice. If a surgeon has not the moral courage to say to himself occasionally 'The interests of this patient are served better by having someone more intimately acquainted with the problem undertake this task than I' when will society or medicine set up an advisory group with authority to decide for us that which we have been unable to decide for ourselves?

Even among teachers of surgery who have a better opportunity for continued self-improvement than the rank and file of surgeons, there are still a few who essay to embrace a large portion of all of surgery. In our time, we have seen the province of the general surgeon shrink so much so that occasionally we wonder what areas of surgery are embraced in the designation general surgery. Yet, this is as it should be. If a teacher of surgery were so ardent a student of his art that he wished to encompass the entire field, an aspiration more ambitious than praiseworthy, he would remain all his days a learner and would thereby lose the important opportunity to give directional growth to a smaller sphere of surgery. Teachers of surgery must prove themselves in the next generation as well as in this. The teacher who leaves no pupils or intellectual progeny has not been fully alive to his responsibilities or wholly faithful to his trust

The passing of the all-around surgical specialist. The sprouting of many surgical specialties from the parent stem of general surgery affords some indication of how surgery has grown. Moreover sharper lines of distinction between the various surgical specialties are being drawn. The specialty boards are playing an important role in lending acceleration to this transition. In some clinics not so long ago one could see a surgeon, in a single day's work, do a stomach operation or two, a few operations upon the biliary tract, as well as the colon and rectum, and perhaps a few gasters and a breast operation or two in addition and then extend himself into the province of the urologist, gynecologist, and orthopedist. Let us be thankful that the day of the all-around surgical specialist is done! Surgery is not advanced by that type of activity and no matter how talented the surgeon he cannot do equally as good work in all these provinces.

The background of training of the surgeon should be broad. But having acquired orientation and competence, a surgeon must of necessity give selective direction to his activity instead of trying to grow in all directions simultaneously. The public has the right to demand a high standard of performance from us. Moreover we are all debtors to our profession and from those of us who have enjoyed opportunities above the ordinary society reasonably may expect that we should strive to add something to the sum total of knowledge rather than continue to be parasites upon our common heritage.

The responsibility of higher institutions of learning to surgery. Surgery has been enriched from many sources. Our institutions of higher learning have a responsibility for leadership in surgical education in this country—not alone to train students for the practice of surgery and to help them meet the requirements of the Specialty Boards, but also for the great task of improving surgery. Recognition of the tremendous importance of research in lending accelerated momentum to the slow growth of knowledge is a part of that responsibility. Knowledge can come to have new meaning with synthesis of well known

facts and much of surgery's progress in the past decade has been compounded out of well known facts becoming known to the right persons. It is to the discovery of new fact however that we look hopefully to the future for significant changes and improvements in surgery that will have the same impact upon our lives as did the discovery of anesthesia and asepsis.

The acquisition of surgical techniques The acquisition of skills is an interesting study. Those of us who have been privileged to be teachers of surgery and who have nurtured young surgical plants have had a unique opportunity to observe how such seedlings grow. Given a good brand of 'plant' with a high native intelligence and a real capacity for application accompanied by an intense and unflagging interest in surgery together with a sympathetic understanding of the frailties of man the capacity for growth of such an individual is almost limitless. And if in addition he is possessed of an inextinguishable yearning to add his bit, whether large or small, to the sum total of surgical knowledge there is no telling how far he may go. That he will surpass his teacher in accomplishment is self-evident. There is a certain inertia or lag in the learning process when progress is made slowly if not almost imperceptibly. But all of a sudden the man who just yesterday seemed almost a novice becomes an accomplished technical surgeon. The circumstances which bring about this accelerated spurt of growth are difficult of assessment and are not readily defined. It is not a process that can be hurried but a development which must come naturally through a certain sequence of events which by no means is the same for all individuals. This development has to do with the surgical neophyte becoming steeped in the practices, techniques and procedures as well as the general approach of a surgical service to problems. In this learning process, acquaintance and an increasing familiarity with the numerous facets of individual surgical problems as they relate themselves to physiology, biochemistry or bacteriology are very important. This period of training constitutes essentially an apprenticeship. For the finished surgeon it is a *sine*

qua non. The surgeon who is self taught is distinguished readily from the person who has pursued this more rigorous and orthodox scheme of training. And how quickly the surgeon of ability who has traveled this devious and stony path learns to master the technical phases of difficult operations is always a source of amazement and gratification to me. It is a metamorphosis in which the co-ordination of eye, mind and hand are important. The man who can grasp the problem and transmit to his hand what the eye sees and exact from this eye to mind to hand relationship a high standard of performance—that man is the superior surgeon. Before this co-ordination is effected the surgeon seemed but a fledgling but when that time comes almost overnight he becomes an accomplished surgeon whose work reflects confidence in his own performance. Only the surgeon who has trod this steep and winding path can know the cost! Is it worth the effort? Ask any of these men and examine the product critically! Truly there is no royal road to learning.

This circumstance of how quickly the trained surgeon masters operative techniques augurs well for the future of surgery. It suggests how we see further than our predecessors because we stand on their shoulders in turn our students stand on ours. It is a promising prospect for surgery the continued growth of which is assured in the hands of the present keen generation of surgeons who are beginning to make their mark. As Leonardo da Vinci remarked: It is a poor pupil who does not surpass his master.

Motivation of the surgeon One need not gossip long in the medical sewing-circle the confessional in which the sins of our neighbors are confessed more adequately than one's own to learn that surgeons are not generally held in that high esteem by our medical colleagues to which we would aspire. There are those who look upon the surgeon as a manual laborer in a Greek dress. There are even those in our own midst who affect to believe there is less science than art in surgery. And many of our medical colleagues who are not as accustomed or as adept as we in employing their hands in the service of their brains are bold to suggest that surgery is only a trade para

sitic upon the generous gifts of medicine. Take away the petty skills from most surgeons they say and see what empty sacks remain. Are these critics unmindful of the tremendous impetus given greater medicine by the discovery of anesthesia and antiseptics? Have they forgotten how the ministrations of the surgeon make an important contribution to the daily enjoyment of and in many instances to the extension of life?

It seems to me that trained surgeons schooled in the scientific method hold in their hands important tools by which to push back the boundaries of medical ignorance. A disciplined imagination lies at the bottom of every great discovery. The most important requisite of any promising research project is an idea. Surgeons who aspire to make contributions to the patrimony of knowledge would do well to school themselves in the techniques of one of the biological sciences, such as bacteriology, biochemistry, or physiology. I hold strongly to the belief that for the surgeon who aspires to a career in academic surgery that 2 years spent in acquiring the technique of one of these provinces of knowledge will pay usurious dividends not alone to the individual but to surgery and greater medicine as well.

The author of a recent thought-provoking and deservedly popular book¹ writes, 'The surgeon's skill sometimes is a splendid example of the sublimation of an early childhood urge to cut. A well known psychiatrist² wrote a few years back 'Leaving aside all secondary conscious motives for operating other than those provided by reality we realize that much surgery betrays evidences of being undisguised sadism. I resent such implied or expressed innuendos concerning the motivations of the surgeon. I associate daily with surgeons who give no evidence of such sadistic repressions. If the truth were known the reasons generally are probably far simpler and find their likely explanation in why men become grocers, lawyers, or engineers. You see before you a boy grown to manhood whose consuming ambition was to continue

his activities on the farm that he loved so much. His discerning father suggested that ministering to the physical ills of man would prove even more satisfying than lavishing care on cows, horses and pigs. This was difficult for a growing farm boy to believe. Inasmuch as the spirit of compromise resolves most differences, I suggested veterinary medicine as a substitute. My father far wiser than I continued to insist that medicine was a better outlet, and so I came rather unwillingly into medicine and surgery pushed in through the back door. "Contented industry and the late Wm. J. Mayo, 'is the making of human happiness. And when that labor has to do with making the lot of man more endurable what employment could give greater happiness?' I feel certain that the services of a psychoanalyst need not be enlisted to ferret out the compelling reasons that urged many of you to become surgeons.

It is, however, probably not out of place to suggest that envy because of the relatively larger incomes earned by surgeons and especially by surgical specialists, lies at the root of much of the criticism directed at surgeons by their medical colleagues. On this score I shall only say that for the years that lie ahead surgeons and other medical specialists paid out of proportion to their contributions to the advancement of medical knowledge, as judged from the critical viewpoint of the true scientist, would do well to consider receiving part of their emolument as increased opportunity. Society rewards us generously for our responsible labors in the relief of suffering and the betterment of man's lot. If however, we value even more the approbation of our colleagues with scientific leanings—a consideration which is not unimportant—some thought might well be lent to utilizing partially the potential earning capacity of surgeons as well as that of other highly paid medical specialists to afford ourselves better conditions of work, thereby improving the product of our labor, and at the same time lending a helpful stimulus to surgery. No doubt, many of you already have resolved this problem in some such manner. Satisfactory conditions of work and an opportunity for creative effort are valued by the thoughtful surgeon as among the best

¹ J. L. Lieberman, *Peace of Mind*, p. 28. New York: Simon Schuster, 1946.
² Karl Menninger, *Psychoanal. Quart.*, 23:4, 3, 1972.

of paymasters. No one fears that the successful surgeon will starve! The tissues of the rich and the poor patient present the same problem to the surgeon. And the inarticulate but touching gratitude of a patient who can not pay in the coin of our realm, is nonetheless among the best of all rewards of the surgeon.
